Given the relatively better fit of this revised feature comparison model, it is important to ask why Rips (1975) did not find evidence for a shift in C_F and we did. One possibility is that the mean of the similarity distribution for the no co-occurrence pairs used by Rips and others (e.g., Meyer, 1970) may have been so low and different from the other distributions that a change in C_F went undetected. The psychological distance be-

[8] If the similarity distributions and cut points are as depicted in Figure 3, we would expect that the mean "true" response times, over all types of trait pairs, should be longer when *all* as opposed to *some* is used as the quantifier. However, the reverse should obtain for the mean "false" response times. This prediction follows from the fact that more fast (single-stage) "true" responses (those above C_T) would be expected with *some* than with *all* as the quantifier. On the other hand, many more long (second-stage) "false" responses would be expected for *some* than for *all* sentences. This pattern of predicted effects was obtained. For universal assertions, the mean "true" response time was 3.85 sec, and the mean "false" time was 3.65 sec, but for particular assertions, the means were 3.61 and 4.16 sec, respectively. The interaction was significant, $F(1, 17) = 6.64$, $p < .05$.

tween an "intelligent" and a "dishonest" person may be much smaller than that between a "woman" and a "chair." One implication of this point is that future research should include evidence about the average similarities of different types of pairs. Unless such evidence is presented, almost any result will be interpretable within the context of the feature comparison model.

The revision in the feature comparison model greatly increases the similarity between what initially appeared to be very different views of implicit personality trait inferences. One of the two crucial aspects that initially differentiated the two models does so no longer, namely, the fact that the criterion for a "false" response varied with the quantifier in the exemplar scanning model and not in the feature comparison model. That is, in the former model we assumed that a change from a universal to a particular quantifier altered the evidence the participant needed for a "false" as well as a "true" response. In the universal case, one negative example was sufficient for a "false" response, but this was not so in the particular case. By allowing C_F to vary, as well as C_T, the same effect is now achieved in the feature comparison model: moderate feature list similarities are sufficient for a "false" response when *all* is used but not when *some* is used.

The commonalities between the two models can be emphasized by noting that both are sensitive to the psychological distance between trait pairs (feature list overlap vs. degree of co-occurrence of attributes in exemplars), and both assume that a different evidentiary criterion is used for "true" than for "false" responses. In the feature comparison model, this last point is made explicit by the dual cut points; however, the exemplar scanning model also postulated a dual criterion (e.g., for particular assertions, the first positive example was sufficient for a "true" response, but a number of negative examples were required for a "false" response). Thus, the two models, while making quite different assumptions about the way in which traits are represented in memory, now predict virtually identical mean reaction time results as a function of alterations in decision criteria because of common processing assumptions.

Experiment 2

It seemed necessary to postulate the existence of a dual-criterion decision process (whether based on features or exemplars) in order to explain the results from Experiment 1. This conclusion greatly limits the class of models that can be used to understand implicit personality inferences of the type being examined here. On the other hand, the evidence for this strong conclusion was not as consistent as we would have liked. For this reason, a second experiment was designed in which more reliable estimates of reaction times and of psychological distances were obtained. The participants were presented with each trait pair six times, three times in one order and three times in the other, both when making binary forced-choice decisions and when rating the similarity of the trait pairs.

Another purpose of this second experiment was to provide evidence relevant to one of the few remaining differential predictions of the two models. Specifically, the exemplar scanning model predicts that the relationship between psychological similarity and "true" and "false" decision times should, in general, vary with the evidentiary criteria used to reach a decision. While "false" times should increase and "true" times should decrease as the similarity increases, regardless of the decision criteria, the absolute value of the *slopes* of these functions should change as the criteria change. When a smaller number of exemplars is required for a false than for a true response (e.g., as in the *all* assertions), the slope for the "false" times should be steeper than for the "true" times. The reverse is expected when a smaller number of exemplars is required for a "true" than for a "false" response. This prediction follows from the fact that the length of a self-terminating search of a sample can extend over a wider range when termination depends on the discovery of a few instances in the sample than when it depends on the discovery of many instances in a sample.[9]

[9] Although this prediction can be tested against the data from Experiment 1, the failure to find significant correlations between similarity and decision time in some conditions prevented a reasonable test from being made.

It should be noted that the revised feature comparison model is quite capable of explaining the pattern described above (were it to be found), provided the distributions of semantic similarities have appropriate forms. Nevertheless, a failure to find the predicted slope changes can be taken as direct evidence against the current version of the exemplar scanning model. Thus, if the predicted changes in slope are found, neither model will receive selective support; but if the predicted changes are not found, the exemplar scanning model, as proposed, can be rejected. Naturally, this prediction need only be examined after other aspects of the results, which are predicted by both models, are found to conform to the common predictions of both models.

As can be seen, an essential aspect of any experiment that attempts to provide evidence relevant to either of the models is that the evidentiary criteria for "true" and for "false" responses be varied in some manner. Rather than repeat the same quantification design used in Experiment 1, we chose to broaden the empirical domain of both models by varying these criteria in a less common manner than is typical of semantic memory research with object categories. Specifically, one half of the participants were asked to verify co-occurrence assertions (in which "a person" was used as a general quantifier), and the other half were asked to verify the similarity of the *dictionary definition* of the trait terms. We assumed that the participants would use a more stringent "true" criterion and a less stringent "false" criterion in the latter than in the former condition. In addition, half of the participants in each of the conditions mentioned above rated the likelihood of the co-occurrence of trait pairs, and half rated their similarity in meaning. This resulted in a 2 (co-occurrence vs. semantic decisions) × 2 (co-occurrence vs. semantic ratings) factorial design.

Method

Subjects

Forty-eight male and female undergraduate college students, who were all native speakers of English, served as participants in exchange for introductory psychology course credit. Six males and six females were randomly assigned to each condition.

Apparatus and Software

The decision times and ratings were collected using a PDP-8A laboratory computer equipped with a video teletype. A user-oriented, experimental-control system, FOEP (Allen, 1978), presented the questions, randomized the trait terms, and recorded the decision times and ratings for later analysis. For both the forced choices and the ratings, the entire question was written onto the video screen at high speed (960 characters/sec).

Procedure

At the beginning of the session, the participants were told that the study dealt with their judgments of various personality characteristics of people. The participants, who were run individually, were then randomly assigned to one of four experimental conditions in which they were asked to make either semantic similarity or co-occurrence ratings and either semantic similarity or co-occurrence binary forced-choice decisions. To provide more stable estimates of the data points, there were three replications for both the ratings and forced-choice decisions. The order of question presentation was randomized for each replication. The order of the ratings and forced-choice judgment tasks was counterbalanced across subjects, and all of the replications for the two tasks were blocked together. The data collection was completed in a 1-hour session.

Semantic similarity and co-occurrence ratings. The question "How similar is the meaning of the trait term _____ to the meaning of the trait term _____?" was used to obtain semantic similarity estimates for all of the trait pairs. The question "How likely is a person who is _____ also to be _____?" was used to obtain co-occurrence estimates. The blanks were completed with all possible combinations of pairs of 10 trait terms. These terms were similar to those used in Experiment 1. For the semantic similarity ratings, the scale was anchored by "not very similar" and "very similar." For the co-occurrence ratings, the scale was anchored by "not very likely" and "very likely." The participants responded by typing a number between 1 and 20, using the digits on the teletype keyboard. For half of the participants, the positive end of the scale was assigned a value of 20; for the other half of the participants, the positive end of the scale was assigned a value of 1.

Forced-choice decision task. The question "Is the meaning of the trait term _____ similar to the meaning of the trait term _____?" was used for the forced-choice semantic decisions, and the question "Is a _____ person also likely to be _____?" was used for the co-occurrence version.[10] The par-

[10] It should be noted that this is a differently quantified statement than those presented in Experiment 1. It seems reasonable that the quantifier *a* would be processed much like the quantifier *a few*. Therefore, relatively little evidence should be required for a "true" response.

ticipants were asked to respond to the questions by pressing one of two teletype keys with their right and left index fingers. The pairing of response key and response direction was balanced across participants. Unlike Experiment 1, the participants in this study were instructed to respond as rapidly but as accurately as possible. It was hoped that this instruction would reduce the variance in decision times. We therefore expected that the average times would be considerably shorter in this study than in the first one.

Each decision trial started with the presentation of the word *ready* on the screen for ½ sec. One-half second after the termination of the ready signal, a question was written on the screen, and the decision time clock was started. When the subject responded, or if no response had been made after 15 sec, the question was erased, and the next trial was started 1 sec later. There was a pause of approximately 1 minute between replications.

Results

Mean Decision Times

As in Experiment 1, the data were analyzed in several different ways. Of initial interest were the effects of question type on the mean "true" and "false" response times. Table 6 presents the average of each subject's mean "true" and mean "false" response times in each condition of the 2 × 2 design. As can be seen, in a manner consistent with both models, people negated semantic assertions faster than they affirmed them; but the reverse was true for the co-occurrence assertions. A 2 (true/false) × 2 (semantic/co-occurrence rating) × 2 (semantic/co-occurrence decision) analysis of variance of the mean decision times indicated that this interaction was highly significant, $F(1, 44) = 29.91$, $p < .001$. There was also a significant tendency for "false" responses to be emitted faster than "true" ones, $F(1, 44) = 4.96$, $p < .05$. No other results were found to be significant. Both models explain the findings mentioned above by assuming that more confirming evidence is needed for a "true" response and less for a "false" response when a semantic rather than a co-occurrence question is asked. Apparently, our attempt to manipulate the true and the false evidentiary criteria was successful.

Table 6
Mean Decision Times (in sec) for Semantic and Co-Occurrence Questions

	Type of response			
	Semantic		Co-occurrence	
Type of rating	True	False	True	False
Semantic	2.085	1.766	2.171	2.254
Co-occurrence	2.201	1.676	1.839	2.103

Table 7
Means of Fisher z Transformed Correlations Between Similarity Ratings and "True" and "False" Decision Times (in log sec)

	Type of response			
	Semantic		Co-occurrence	
Type of rating	True	False	True	False
Semantic	−.26	.35	−.21	.29
Co-occurrence	−.33	.18	−.20	.22

Decision Times and Similarity

One of the most important predictions of both models, which yielded ambiguous results in Experiment 1, concerns the relationship between psychological similarity and "true" versus "false" decision times. In the present experiment, both models predict a negative relationship for "true" response times and a positive one for "false" response times. Table 7 presents the mean correlation for each condition in the 2 × 2 design. Correlations were computed for each subject by taking the mean decision time for the three replications for each trait pair and treating the different orders of trait terms in a pair as unique observations. The "true" and "false" means were then separately correlated with the associated mean similarity ratings for corresponding orders. Not only was the pattern of correlations exactly as predicted, but in addition, with the more sensitive procedure used in Experiment 2, all of the average correlations were significantly different from zero, minimum $t(11) = -2.51$, $p < .05$.

A 2 (true/false) × 2 (semantic/co-occurrence rating) × 2 (semantic/co-occurrence decision) analysis of variance of the results indicated that the true/false difference was highly significant, $F(1, 44) = 252.11$, $p < .0001$. No other effects were found to be sig-

nificant. In short, as predicted by both models, "false" response times increased and "true" response times decreased as the similarity of the pairs increased, whether the similarities of the pairs were measured by semantic overlap or trait co-occurrence, and whether the decision times were produced from verification of a semantic or a co-occurrence assertion.

The previous analyses had established the necessary conditions for an examination of the effects of criteria alterations on the slopes of the relationship between reaction times and similarity. These slopes were computed separately for each subject in the same fashion as were the correlations. A $2 \times 2 \times 2$ analysis of variance of these data indicated that the interaction between true/false and type of question predicted by the exemplar scanning model was not significant ($F < 1$). No other effects were significant. Apparently, the mean absolute values of the slopes were the same in all conditions.

General Discussion

The results from both experiments can be easily summarized. First, when an assertion about a pair of traits was altered (either by changing the quantifier or by changing the nature of the assertion), such that greater psychological similarity was required for a positive response, the time to reach a positive decision increased, and the time to reach a negative decision decreased (Tables 2 and 6). Second, as the psychological similarity between trait terms (whether assessed by definitional or co-occurrence ratings) increased, the latency of positive decisions about the two traits decreased, and the latency of negative decisions increased (Tables 3 and 7). Third, the strength of the relationships between psychological similarity and "true" and "false" latencies did not vary as the evidentiary criteria varied. Taken together, these results seem more consistent with the revised feature comparison model than with the exemplar scanning model.

The former model explains the findings summarized above by postulating a two-stage decision process in which some decisions are made after a first stage, whereas others are made after a second stage. The more time-consuming second-stage processing is required when the similarity of the two feature lists falls in between a "true" and a "false" cut point. The placement of *both* cut points depends on the exact nature of the assertion. The relationship between similarity and "true" and "false" response times follows from the fact that an increase in similarity increases the probability that "false" responses will result from second-stage processing and decreases that probability for "true" responses. The effects of quantifier and type of assertion are explained in terms of shifting cut points.

Given the intuitive plausibility of an exemplar representation of traits, it is important to ask whether the exemplar scanning model can be revised in a manner that retains this representation of traits but which does not predict the slope interaction. One possibility is to alter our assumptions about decision processes. Assume that subjects take more than one exemplar from memory and that their "true"/"false" decision is based on whether the overall *proportion* of X exemplars with the Y trait is greater than a "true" criterion or less than a (different) "false" criterion. Suppose further that subjects will continue to draw samples until the overall proportion is above the "true" or below the "false" cut point. Finally, assume that decision times are an increasing function of the number of samples that are drawn. This model does not predict the slope changes. It also makes decision time predictions that are identical to the feature comparison model. In fact, it should be obvious that the two new models assume virtually identical decision processes and differ primarily in the way in which trait terms are represented in memory, and therefore in the dimension that underlies the true/false criterial decision.

While the exemplar scanning model can perhaps be salvaged with the modifications suggested above, it is important to realize that the data have constrained that model so that the decision processes in this new model have much in common with those of the feature comparison model. Although it appears that we cannot decide from the data pre-

sented here whether traits are represented in memory as feature lists, exemplars, or even both, consistent with the original goal of this research, we can conclude that (a) whatever the mental representation of traits may be, the similarity of those representations seems to play a major role in implicit personality inferences; (b) decisions about people's personality characteristics seem to be governed by a multistage process in which some answers are based on a less extensive (or detailed) search of memory than other answers (the search is not exhaustive in all cases); (c) a different criterion seems to be used for "true" than for "false" responses; and (d) *both* evidentiary criteria seem to change as the nature of the assertion changes. Thus, models that argue that all decisions are made after an exhaustive scan or processing of the relevant evidence cannot explain the current results. Such models would, in general, not be able to explain the effects of quantification on decision times found in these experiments. Similarly, models that assume that exhaustive scans or processing occur as a default option when sufficient evidence for a "true" response is not found (e.g., Collins & Quillian, 1969) are incapable of explaining the changes in mean "false" response times observed in both experiments.

On the other hand, almost any view of the representation of trait terms (e.g., prototype, schema, script, network, feature list, set of exemplars, visual image, etc.) could be postulated and combined with a multistage processing model similar to that described here, so as to explain the results from these experiments. This fact suggests the need for caution when claiming that social information takes a particular form in memory. As we noted in the introduction, most models of cognitive–social phenomena include assumptions about the structure of information in memory, the mechanisms by which that information is retrieved from memory, and the decision process that operates on that information. It can happen, therefore, that very different assumptions about one or more of these aspects of semantic decisions can yield identical predictions, provided other aspects of the model take an appropriate form (see Anderson, 1978, and Townsend, 1974, for similar views). For this reason, we believe caution must be exercised when concluding that a given set of results validates a particular structural view or a particular retrieval process.

It is of interest to note that a process model that provides a useful explanation of implicit personality inferences also provides a useful explanation of decisions about entirely different kinds of semantic information. Apparently, the same model can be used to understand how people decide whether a mother is a chair as whether an intelligent person is also honest. The same model also seems to apply to other social stereotypes besides traits. For example, Cohen (1977) reported results of a reaction time experiment in which people decided whether particular attributes were characteristic of given occupations. "False" reaction times increased and "true" reaction times decreased as the rated typicality of the attribute to the occupation increased. It even appears that decisions about the relevance of particular attributes to oneself are governed by a dual-criterion multistage decision process. Markus (1977) found that reaction times for "like me" decisions about trait attributes decreased as the rated self-applicability of the trait terms increased. In short, there is reason to believe that questions about semantic information, whether that information is about traits, objects, occupations, oneself, or something else, seem to be answered by a multistage process in which the similarity of the elements in the question is compared to task-established evidentiary criteria.

It is both somewhat surprising and important that the present dual-criterion multistage model appears to have such wide generality. As mentioned above, it seems likely that similar, if not identical, processes may be found for a variety of social psychological inference processes besides those involved in implicit personality inferences.

Effects of Exogenous Changes in Heart Rate on Facilitation of Thought and Resistance to Persuasion

John T. Cacioppo
University of Notre Dame

Two experiments were conducted to examine the effects of an accelerated heart rate on information processing and resistance to persuasion. Experiment 1 addressed the effects on cognitive performance of manipulating heart rate exogenously for brief periods of time. Fourteen subjects wearing implanted demand-type cardiac pacemakers performed reading comprehension and sentence generation tasks while their heart rate was either accelerated or not accelerated. Results revealed that performance was better when heart rate was accelerated than when it was not accelerated. Experiment 2 addressed the effects on counterargumentation and resistance to persuasion of manipulating heart rate using the cardiac-pacing technique employed in Experiment 1. Subjects read highly involving counterattitudinal communications while their heart rate was either ostensibly or actually accelerated. Accelerated heart rate resulted in the generation of more total thoughts and counterarguments than did basal heart rate; resistance to persuasion was related significantly to the number of counterarguments generated. The methodology used provides a means by which social psychologists can study the effects on social processes of actual but unperceived changes in physiological processes.

Much of our social behavior is affected by the state of our physiological systems. The important work on this issue by social psychologists has been concerned with the effects on cognition and behavior of *perceived* changes in the functioning of the autonomic nervous system (ANS; e.g., Detweiler & Zanna, 1976; Schachter, 1964; Valins, 1966). However, little has been done with respect to the effects of *actual* but *unperceived* changes in ANS functioning. Methodological rather than theoretical problems seem responsible for this empirical deficit (cf. J. Lacey, 1967; J. Lacey & B. Lacey, 1974). Recently, a technique has been found (Cacioppo, 1977) that may alleviate the latter shortcoming. The purpose of this article is to describe this procedure as well as to demonstrate that heart rate influences cognitive elaboration. This will be done in two ways: (a) by showing that performance on an intellectual task requiring cognitive elaboration is enhanced by increased heart rate (Experiment 1) and (b) by showing that when resistance to persuasion depends on cognitive elaboration, greater resistance (counterarguing) occurs with high heart rates (Experiment 2).

Cardiac Activity and Information Processing

Angell and Thompson (1899) were perhaps the first to conclude that performing complex cognitive tasks led to an accelerated heart rate. Somewhat later, Darrow (1929a) dis-

This article is based on a doctoral dissertation submitted to the Department of Psychology of the Ohio State University. I am especially grateful to Anthony G. Greenwald, Richard E. Petty, Curt A. Sandman, Timothy C. Brock, and D. Chris Anderson for their comments on an earlier draft of this manuscript, to Charles V. Meckstroth, M.D., for providing subjects and for medical supervision during the research, and to Douglas Lundy for serving as the experimenter in Experiment 2.

Parts of the article were presented at the meeting of the American Psychological Association, San Francisco, August 1977, and at the meeting of the American Association for the Advancement of Science, Washington, D.C., February 1978.

Requests for reprints should be sent to John T. Cacioppo, Department of Psychology, University of Notre Dame, Notre Dame, Indiana 46556.

tinguished between stimuli that led to "excitation of sensory end organs causing immediate physiological effects but calling for no extensive association of ideas" from those that led to "excitation in which the stimulation of sensory end organs is but incidental to the initiation of associative processes" (p. 185). He concluded from a review of the literature that (a) momentary sensory stimulation was accompanied generally by a decelerated heart rate and (b) "ideational stimuli" were associated with an accelerated heart rate. This review and an experimental study by Darrow (1929b) were followed by a lull of almost three decades in this area of research (J. Lacey, 1959; J. Lacey & B. Lacey, 1958).

Contemporary investigations of cardiovascular psychophysiology have included (a) monitoring heart rate during the anticipation and performance of a wide variety of cognitive (e.g., sentence generation) and sensory (e.g., viewing flashing lights) tasks (see J. Lacey, 1959; J. Lacey, Kagan, B. Lacey, & Moss, 1963; Obrist, 1963); (b) the measurement of the differences in heart rate change during performance by individuals who differ dispositionally in their mode of processing task information (e.g., Blatt, 1961; Kagan & Rosman, 1964); (c) the manipulation of attributes of the task while monitoring heart rate (e.g., Cacioppo & Sandman, 1978; Campos & Johnson, 1967; B. Lacey & J. Lacey, 1974; Tursky, Schwartz, & Crider, 1970); (d) monitoring heart rate *and* somatic activity during the anticipation and performance of tasks, often under varying levels of motivation (e.g., Elliott, 1974; Obrist et al., 1974); and (e) monitoring sensory thresholds, reaction time, or cognitive and attitudinal responses following endogenous changes in heart rate (e.g., Cacioppo, Sandman, & Walker, 1978; Sandman, McCanne, Kaiser, & Diamond, 1977; Surwillo, 1971).

Methodological Considerations

Although heart rate has been found generally to covary with the cognitive complexity, or difficulty, of a task (e.g., Cacioppo, 1977), the biological basis of this association has been and continues to be debated. The Laceys (J. Lacey, 1967; J. Lacey & B. Lacey, 1958) have formulated a neurophysiological account of the variations of heart rate observed during these tasks. They have speculated that, ceteris paribus, an accelerated heart rate is associated with and facilitates cognitive elaboration, whereas a decelerated heart rate is associated with and facilitates sensory reception. Obrist and his colleagues (Obrist, Gaebelein, Shanks, Langer, & Botticelli, 1976; Obrist, Webb, Sutterer, & Howard, 1970), however, have contended that the observed changes in heart rate are accompanied by changes in somatic activity, both of which are mediated by a common central nervous system (CNS) integrating mechanism. Unfortunately, most of the research with humans on which these writers base their arguments is correlational rather than experimental.

Several design strategies might be adopted to provide information about the effects of changes in heart rate on information processing. For instance, heart rate might be varied exogenously without the individual's knowledge, to determine if changes in heart rate are sufficient for altering information processing; [1] or physiological activity except for heart rate could be varied systematically to determine if changes in heart rate are necessary for altering information processing.

The first strategy was adopted in the present research. In Experiment 1, cardiac-pacing techniques were employed to accelerate heart rate during the performance of two cognitive tasks (reading comprehension and sentence generation). These procedures involve only minimal risks; nevertheless, the research was conducted in a clinical setting under the supervision of a cardiologist. Unfortunately,

[1] Exogenous manipulations of heart rate are more appropriate for investigating causal relationships between changes in heart rate and cognitive/sensory behavior because (a) exogenous manipulations of heart rate can be accomplished without the subject knowing when and in what direction heart rate was varied, thus circumventing the confounding effects of the subject's knowledge or belief of heart rate changes (cf. Valins, 1966); and (b) if behavioral effects are observed to result from an exogenous change in heart rate, then causal direction of the observed association is established.

this setting contained no resources for the measurement of any physiological process besides heart rate, but previous research has demonstrated that paced changes in heart rate (within the range of rates employed in the present research—i.e., 72–88 beats per minute) are unaccompanied by significant changes in normal visceral, somatic, or cardiac-output responses (e.g., Gill, Jakobi, Morton, & Wechsler, 1975; Karlof, Bevegard, & Ovenfors, 1973).

The selection of heart rates for investigation and the length of the experimental sessions in this research also were restricted. The pacemaker worn by each subject had been implanted for at least 3 months and was necessary to maintain heart rate in most instances at 72 beats per minute (bpm).[2] Except for surgical procedures, paced heart rate could be changed only by the use of a magnet, which, when placed properly, immediately accelerated and maintained heart rate at 88 bpm. Thus, although it would have been desirable, the effects of a decelerated heart rate on performance could not be studied in this research. And time limitations restricted the type and number of tasks on which observations could be made.

Complex cognitive tasks were chosen for the present study because of the theory and research that suggest that an accelerated heart rate should facilitate performance on these tasks (e.g., J. Lacey, 1967; J. Lacey et al., 1963). The sentence generation task has been used in previous research and was found to be associated with an accelerated heart rate (J. Lacey et al., 1963). A task similar to reading comprehension was employed by Spence, Lugo, and Youdin (1972): Subjects were instructed to attend to, and were later asked to recall, sentences reflecting a certain theme while they listened to a 17-minute passage from a clinical interview. Spence et al. found that subjects displayed a decelerated heart rate (presumably denoting sensory intake) followed by an accelerated heart rate (presumably denoting cognitive elaboration or encoding) during the presentation of thematic sentences that were subsequently recalled. This waveform was distinct from those displayed in the absence of thematic sentences and in the presence of unrecalled thematic sentences. Since the present procedure allowed the subject to take as long as he or she wished to read the passages (hence, allowing subjects to control sensory intake by their allocation of reading time to items), we expected that an accelerated heart rate would facilitate the cognitive elaboration, or encoding, of the stimuli and thereby improve reading comprehension.

Experiment 1

Method

Subjects. Eighteen healthy and articulate outpatients at a large midwestern university hospital volunteered to participate in the experiment. Each subject had worn a permanently implanted demand-type cardiac pacemaker for at least 3 months prior to participation in the experiment. All subjects were examined by a cardiologist and, immediately afterwards, were given a pretest by the experimenter. Four subjects were not included in analyses: (a) One could not read; (b) one was extremely nervous and refused to follow instructions once the experiment had begun; (c) one was reading a passage when her daughter entered the testing room and began speaking with her; and (d) one was replaced because the placement of the magnet to increase heart rate could not be determined by the experimenter. The remaining 14 subjects completed the pretest satisfactorily: Each displayed (a) a basal heart rate of 72 bpm when a capped magnet was placed over a reed of the pacemaker, (b) an accelerated heart rate of 88 bpm when an uncapped magnet was placed over a reed of the pacemaker, and (c) an inability to identify the intervals during which heart rate was accelerated (as determined by questions asked of the subject during the pretest).

---

[2] Cardiac Pacemakers, Inc. (CPI) was the manufacturer of the pacemakers. The demand-type pacemaker is characterized by its pacing of a person's heart rate at a constant rate when natural pacing produces a rate below the preset level of the cardiac pacemaker. To our knowledge, this is the only pacemaker that provides a nonsurgical means of altering heart rate simply, exogenously, and without the subject's awareness. The preset level of the CPI pacemakers used in the present study was 72 bpm. The subjects employed in Experiments 1 and 2 required cardiac pacing when seated to attain a heart rate of 72 bpm.

Importantly, subjects in the present experiments were unable to report accurately when and how frequently their pacemaker was pulsing their heart. This finding is consistent with that of Nowlin, Eisdorfer, Whalen, and Troyer (1971); they reported subjects were unaware of paced changes in heart rate that exceeded 110 bpm.

Subjects were told to discontinue their participation at any time they wished. Four subjects left after their completion of the first series of tests (i.e., the reading comprehension test); reasons for leaving included feeling fatigued, feeling nervous, and being late for another appointment.

Materials and apparatus. Two types of cognitive tests were administered. The instructions, example passage and questions, and four test passages and questions were selected from a college-level reading comprehension test for use in the first portion of the experiment. In the second portion of the experiment, a sentence generation task was employed. The task involved spending 90 sec generating sentences that (a) consisted of exactly five words, (b) made sense, (c) had good grammatical structure, (d) consisted of at least three words not contained in a previous sentence, and (e) began with the same letter. (The letter for the practice trial was *O;* the first test-trial letter was *E;* and the letter used for the second test trial was *A*.) An Apollo stopwatch was used to time subjects during the tasks, and a CPI horseshoe magnet was used to manipulate heart rate.

Design. A 2×2 factorial design was used. Heart rate (basal vs. accelerated) served as a within-subjects factor, and the order in which heart rate was varied served as a between-subjects factor. The tasks were administered in the same sequence to all subjects. However, half of the subjects (a) read the first and third passages of the reading comprehension test and (b) performed the first test trial of the sentence generation task with a basal heart rate of 72 bpm; these subjects (c) read the second and fourth passages of the reading comprehension test and (d) performed the second test trial of the sentence generation task with an accelerated heart rate of 88 bpm. The heart rate of the remaining subjects was varied in the opposite sequence during the tasks. Subjects were assigned randomly to the order condition. (Passages served as an additional within-subjects factor for the analyses of the reading comprehension measures.)

Procedure. Subjects were tested individually while sitting calmly at a table in a quiet room. The experimental tasks were described, and an example passage and questions for the reading comprehension test were administered. Once subjects understood what they were to do and were relaxed with the procedure, the reading comprehension test was administered.

Either a capped (basal heart rate) or uncapped (accelerated heart rate) magnet was placed over a reed of the subject's pacemaker while he or she read each practice and test passage.[3] Immediately following the subject's response that he or she had completed reading the passage, the magnet was removed, the next page of the booklet was presented, and the subject answered the multiple-choice questions about the passage just read. Subjects were allowed to take as long as they wished to read each passage and answer the subsequent questions, but subjects were not allowed to return to a passage once they had reported having read it. Four passages and multiple-choice tests constituted the reading comprehension test.

Next, the nature of and instructions for the sentence generation task were explained. Subjects practiced the procedure until the requirements of the task were understood. Each subject's heart rate was monitored, and either a capped or uncapped magnet was placed over the pacemaker during the 90 sec in which sentences were generated. At the onset of the trial, the experimenter announced the letter with which each sentence was to begin, and during the trial, subjects listed the sentences on ruled paper as they generated them.

Dependent variables. The percentage of the questions for each passage that was answered correctly served as the measure of reading comprehension; the time that was spent reading each passage was also recorded and analyzed.

The dependent measure of the sentence generation task was calculated in the following manner: (a) Each sentence that was generated in accordance with all of the instructions listed was assigned a value of 1.0; (b) sentences with errors were assigned a value of $(1.0 - .2X)$, where X denoted the number of errors (0 was the least a sentence could be assigned).[4] The total points accumulated served as the measure of cognitive performance.

Results and Discussion

Fourteen subjects completed the reading comprehension task, and 10 of the 14 subjects completed the sentence generation task. A multivariate analysis of variance was conducted for the cognitive performance of the 10 subjects who completed the experiment; the dependent measures were the percentage of correct answers in the reading comprehension test and the number of points accumulated in the sentence generation task. The analyses indicated that accelerated heart rate facilitated performance, $F(3, 6) = 5.63$, $p < .05$.

Univariate analyses of variance revealed

---

[3] Since pacemakers are sometimes implanted in other than the upright position, location of the reed was determined by monitoring heart rate while placing the magnet on the skin over the upper and lower portions of the implanted pacemaker. When placement of the magnet resulted in an accelerated heart rate of 88 bpm, the placement was marked with a felt pen. Heart rate was also monitored during the pretest and test intervals. In all instances, heart rate did not vary from the paced levels.

[4] The person who scored the sentences was blind to the experimental conditions to which the subject had been assigned.

that (a) reading comprehension was better during accelerated heart rate ($M = 48.68\%$) than during basal heart rate ($M = 39.33\%$), $F(1, 12) = 5.24$, $p < .025$, one-tailed comparison; (b) performance of the sentence task was improved marginally by accelerated heart rate ($M = 3.88$) compared to basal heart rate ($M = 3.27$), $F(1, 8) = 2.87$, $p < .08$, one-tailed comparison; and (c) reading time was not affected by heart rate or order ($Fs < 1$).

A significant Heart Rate × Order interaction, $F(1, 12) = 51.68$, $p < .01$, for reading time signified that the second and fourth passages of the reading comprehension test ($M = 78.1$ sec) took longer to read, on the average, than did the first and third passages ($M = 45.4$ sec). Since this interaction was not significant for the percentage of correct answers on the reading comprehension test ($F < 1$), these results indicate that reading time did not affect the role of heart rate on cognitive performance in the present study.

Together, these results indicate that heart rate accelerated peripherally is sufficient to facilitate performance of a difficult cognitive task when the change in heart rate is brief (e.g., 30–90 sec) and ongoing physiological activity reflects a normal state.[5]

Experiment 2

Previously, multiple sessions of discriminative operant training have been employed to modify heart rate while subjects maintained a relatively constant level of somatic and respiratory activity (Cacioppo et al., 1978). The results revealed that individuals generated more counterarguments and were more resistant to persuasion when heart rate was accelerated than when it was decelerated. It appeared that brief accelerations of heart rate when unaccompanied by large increases in somatic activity produced resistance to persuasion by stimulating the cognitive elaboration of and responding to the counterattitudinal communication. Thus, it was expected that the brief increase in heart rate produced by using cardiac-pacing techniques would facilitate thought production (e.g., counterargumentation) and, ultimately, resistance to persuasion. The purpose of Experiment 2 was to provide a direct test of this hypothesis.

Method

Subjects. Twenty-four healthy and articulate outpatients at a large midwestern university hospital volunteered to participate in the experiment. Experiment 2 was conducted in the same setting and in a similar manner to Experiment 1. As before, subjects were examined first by their cardiologist and by an experimenter who was unaware of the experimental hypotheses. Each subject displayed (a) a basal heart rate of 72 bpm when a capped magnet was placed over a reed of the pacemaker, (b) an accelerated heart rate of 88 bpm when an uncapped magnet was placed over the reed of the pacemaker, and (c) an unawareness of the intervals in which heart rate was manipulated. Two subjects were deleted from analyses because the experimenter failed to follow the experimental procedure correctly.

Materials and apparatus. Subjects were given the first half of the reading comprehension test employed in Experiment 1 during a preliminary examination and instruction period. These stimuli constituted the materials used in the preliminary task. Materials for the experimental task were developed in pilot testing with four elderly subjects; communications were developed that were highly involving and counterattitudinal. The advocacies selected were that (a) all Social Security and Medicare programs be eliminated and (b) the drinking and voting age in Ohio be lowered to 13 years of age.

CPI horseshoe magnet again was used to close the reed in the pacemaker and thus raise heart rate, and an Apollo stopwatch was used to time reading intervals.

Design. A 2 × 2 factorial design was used. Heart rate (basal vs. accelerated) served as the within-subjects factor, and the order in which heart rate was varied (basal–accelerated vs. accelerated–basal)

---

[5] To assess if it was necessary to vary heart rate within a constant pattern of peripheral nervous system activity to affect cognitive performance, a portion of the experiment was replicated using college undergraduates who had no pacemakers. They either stood or lay down while performing a reading comprehension task; these postural variations caused not only heart rate to differ but also respiration, muscle tension, and blood pressure. In this situation neither reading time nor reading comprehension was affected by the heart rate of the subject during the performance of the task. One should be cautious in comparing these results with the previous experimental results because of the noncomparability of the subject samples. Nevertheless, these studies together suggest that increased heart rate facilitates cognitive performance, particularly if the increase is relatively independent of major changes in physiological activity.

served as the between-subjects factor. Again, the stimuli were presented to all subjects in the same sequence.

Procedure. The procedure was similar to that used in Experiment 1 except that subjects engaged in a longer preliminary task to all adaptation to the experimental procedures prior to the administration of the experimental task. Subjects were tested individually while sitting at a table in a quiet room. Subjects were told that they would first read two passages and answer questions about the content of each passage; afterwards, they would hear two advocacies, and their opinions about each would be solicited.

The preliminary task was then begun. Two passages of the reading comprehension test were administered. During the performance of the preliminary task, (a) heart rate while a capped and uncapped magnet was placed over a reed of the pacemaker was again determined; (b) task requirements were clarified; and (c) all subjects were assured that the changes in their heart rate were not hazardous to their health. (Greater precautions were taken in the present experiment than in Experiment 1 because of the involving nature of the experimental task.)

Subjects then performed the experimental task. Subjects were informed that two proposals pertinent to them were under consideration and that messages had been prepared to explain the proposals. Subjects read each advocacy at their own speed. After reading each, subjects were given 2.5 min. to list everything about which they had thought while reading (thoughts were reported aloud by speaking into a tape recorder) and were asked to rate their agreement with the advocacy.[6]

Dependent variables. The tape-recorded listings of thoughts were transcribed by a judge who was unaware of the experimental hypotheses. Transcribed as a "cognitive response" was any phrase or sentence expressing a single thought or idea; although grammar was not a criterion, a subject's pauses and voice inflections were used in a few instances to determine whether a phrase or a group of phrases was a single thought or idea. The total number of thoughts and ideas listed served as a measure of the amount of cognitive responding.

A second judge, unaware of the experimental conditions to which a subject was assigned, scored the transcribed cognitive responses. Each response was scored as favorable, unfavorable (i.e., counterargument), or neutral/irrelevant toward the advocacy.[7] A third judge, who also was unaware of the experimental conditions to which subjects were assigned, spot-checked the scoring of cognitive responses. The second and third judges agreed completely on the scoring of the responses. (This was due largely to the uniform nature of the responses generated—see discussion below).

The subjects were asked, "How much do you agree with the proposal that you just read about?" after listing their responses to each advocacy. Subjects responded to the question using a 15-point scale in which 1 was labeled "disagree completely" and 15 was labeled "agree completely."

Although there were procedural differences among the subjects during the preliminary task of this experiment, the percentage of questions answered correctly and the reading time were also monitored and analyzed.

Results

Twenty-two subjects completed the preliminary and experimental tasks. Multivariate analyses of variance were performed for the set of eight dependent measures; heart rate and order served as the criteria. The analyses revealed that heart rate affected cognitive and affective response, $F(8, 13) = 3.17$, $p < .05$. Univariate analyses of variance were then performed. The means are summarized in Table 1.

Preliminary task. Neither heart rate nor order affected reading comprehension or reading time during the preliminary task. Heart Rate × Order interactions were found for both reading comprehension, $F(1, 20) = 7.39$, $p < .05$, and reading time, $F(1, 20) = 11.65$, $p < .01$. These effects denoted only that the first passage was read more quickly and comprehended less completely than the second passage (see Table 1). This result is due possibly to the subjects' apprehension

---

[6] Subjects were asked to verbally report everything about which they thought during their reading of the advocacy, because pilot testing indicated subjects had noticeable difficulty in writing. This difficulty was also noted during Experiment 1, and may possibly account for the attenuated effects of heart rate on the performance of the sentence generation task observed in Experiment 1.

[7] The procedures employed for scoring were adapted from Petty and Cacioppo (1977) and Cacioppo and Petty (1979). Statements directed against the advocated position that mentioned specific unfavorable consequences, statements of alternative methods, challenges to the validity of arguments in the message, and statements of affect opposing the advocated position were counted as counterarguments. Statements in favor of the advocated position that mentioned specific favorable consequences, statements eliminating alternatives, statements that supported the validity of the message, and statements of positive affect regarding the advocacy we scored as favorable thoughts. All other statements were classified as neutral/irrelevant thoughts.

Table 1
Summary of Cognitive Measures for Preliminary and Experimental Tasks, Experiment 2

Measure	Heart rate			
	Basal (72 beats per minute)		Accelerated (88 beats per minute)	
	Order 1 (Message 2)	Order 2 (Message 1)	Order 1 (Message 1)	Order 2 (Message 2)
Preliminary task				
Reading comprehension	41.73	26.36	19.73	38.91
Reading time	96.73	47.54	47.36	92.91
Experimental task				
Total thoughts	3.82	3.00	4.82	3.55
Counterarguments	3.73	2.91	4.73	3.27
Favorable thoughts	.09	0	0	0
Neutral/irrelevant thoughts	0	.09	.09	.27
Attitude	1.67	3.82	1.91	3.36
Reading time	145.00	121.64	134.82	138.64

Note. Entries for reading comprehension are in terms of percentage of correct answers, whereas entries for reading time are in seconds. Higher means on the attitude measure indicate more agreement with the speaker's position, where 1 indicates "disagree completely" and 15 indicates "agree completely." Remaining entries designate the mean frequency observed for each type of cognitive response measured.

about the experiment and confusion about what they were to do when they started.

Experimental task. It was hypothesized that an accelerated heart rate would facilitate cognitive responding. The analyses supported the hypothesis: More total thoughts, $F(1, 20) = 20.64$, $p < .001$, and counterarguments, $F(1, 20) = 12.36$, $p < .01$, were produced when heart rate was accelerated than when it was not accelerated (see Table 1).

It was also hypothesized that heart rate would affect resistance to persuasion. The analysis of variance provided no support for this hypothesis: No treatment or interaction of treatments affected subjects' rating of agreement with the advocacies. However, an inspection of the raw data revealed that 59% of the subjects' responses to the attitude measure were 1 ("disagree completely"); thus, the attitude measure was probably insensitive to treatment effects. In other words, subjects were able to counterargue and reject completely the advocacies, whether their heart rate was accelerated (thus, facilitating cognitive responding) or not accelerated. Accordingly, a total of one favorable thought and five neutral/irrelevant thoughts were generated during the entire experiment. Within-cell correlations between the cognitive response and attitude measures were calculated and indicated that agreement with the advocacy was related (a) negatively with the number of counterarguments generated ($r = -.46$, $p < .05$); (b) positively with the number of neutral/irrelevant thoughts generated ($r = .42$, $p < .05$); and (c) negatively with the number of total thoughts generated ($r = -.44$, $p < .05$). Counterargumentation and total thoughts were correlated positively and highly ($r = .99$, $p < .001$), denoting that most of the thoughts generated were unfavorable toward the advocacies (see Table 1). Finally, counterargumentation and the number of neutral/irrelevant thoughts were related negatively ($r = -.35$, $p < .05$).

The positive association between the number of neutral/irrelevant thoughts generated and susceptibility to persuasion was unexpected. The production of neutral/irrelevant thoughts may indicate that a person was momentarily or partially distracted from responding cognitively to the advocacy while reading. Previous research has demonstrated that distraction during the presentation of a counterattitudinal communication increases susceptibility to persuasion by inhibiting the production of counterarguments (cf. Petty, Wells, & Brock, 1976). Thus, the generation

Encoding of Personal Information: Self–Other Differences

N. A. Kuiper
University of Calgary, Calgary, Canada, and
University of Western Ontario, London, Canada

T. B. Rogers
University of Calgary, Calgary, Canada

Self–other differences in processing personal information were investigated by having subjects make self-referent (describes you?) or other-referent (describes experimenter?) ratings of personal adjectives. Results from five studies indicated that self-ratings were consistently judged as easier to make, and subjects always placed more confidence in these judgments. An analysis of rating times showed that only adjectives with long rating times were recalled for the unknown-other-referent task (Experiments 2 and 3). In contrast, the recalled words for the self-referent task had very short rating times. This difference is explained via a "two-process" interpretation. Unknown-other-referent processing involves a relatively inefficient rehearsal or effort strategy, whereas self-referent processing involves the self as a highly organized and efficient schema. Finally, the effects of familiarity on other-referent processing were examined. A model of other processing is formulated to account for the observed changes in processing information about a familiar other (Experiments 4 and 5).

The present article is concerned with how information about the self and others is processed. The focal concern is upon the kinds of memory traces produced by judgments about the self and judgments about others. Our major goal is to delineate processing differences between these two kinds of judgments.

Some recent research and theory in personality and social psychology has been concerned with how people process personal information (Cantor & Mischel, 1977; Markus, 1977; Rogers, Kuiper, & Kirker, 1977; Ross, 1977). These researchers have begun to map out some of the biases and facilitations that emerge when people process input data about themselves and others. Some of the findings include the following (a) Adjectives processed using self-reference produce extremely deep and elaborate memory encodings (Rogers et al., 1977); (b) subjects can produce more behavioral exemplars for traits that they themselves possess (Markus, 1977); (c) there are several kinds of biases in recognition memory that are related to the personality of either a target person (Cantor & Mischel, 1977) or the subject (Rogers, Rogers, & Kuiper, in press); and (d) resistance to incorrect personal data is related to self-perception (Markus, 1977). Each of these findings sheds some light on the kinds of transformations that occur to personal data as they are absorbed into the human cognitive system.

The Role of Cognitive Prototypes or Schemata

The theoretical notion of prototype or schema has been advanced to account for the findings mentioned above. For example, Markus (1977) postulates that a person's organization, summation, and explanation of personal data involve the use of "self-schemata," which are "cognitive generalizations

The research reported herein was supported by a grant from the Canada Council. We thank Scott Kirker, Gloria Miller, and Ed Hansen for comments on earlier drafts and Barb Blakemore, Laurie Williams and Scott Kirker for their help in running subjects and data analysis.

about the self, derived from past experience, that organize and guide the processing of self-related information" (p. 63). These schemata or cognitive structures are thought to interact with incoming data and produce some of the biasing and facilitating effects outlined earlier. For example, Cantor and Mischel (1977) showed subjects a series of statements describing an introvert (as well as some other statements). The subjects were then shown a list of items and asked to indicate whether each item had been in the first series of statements. These subjects showed a consistent bias to identify novel, but highly introvert-related, items as having been in the first series, when they had not. These data indicate that the subjects had abstracted the concept of introvert during the initial list presentation and used this abstraction as a comparator or reference during the identification task. When novel items representing similarity to this abstraction were presented, the subjects tended to misidentify them. The abstraction represents a prototype or schema, and its biasing effect on information processing is clearly reflected in the Cantor and Mischel data (see also Rogers et al., in press). The notion of schema or prototype has found support in most of the work concerned with processing personal data (e.g., Markus, 1977; Rogers et al., 1977).

Schemata or prototypes have been postulated to underlie processing of other kinds of information as well. For example, Posner and Keele (1970) demonstrate biases, not unlike those shown by Cantor and Mischel (1977), in a pattern recognition situation. Memory for connected discourse (Bartlett, 1932), faces (Reed, 1972), and embedded sentences (Bransford & Franks, 1971) has been interpreted using schemata or prototypes as the major theoretical construct.

Self–Other Differences in Processing Personal Information

The present article is concerned with the kinds of structures that are involved in processing information about other people. It is assumed that some kind of cognitive structure—possibly a schema or prototype—is involved when we process information about others. The critical question is whether these "other structures" are any different from the "self-schema" documented in the previously outlined research. In an effort to explore this question, the present article involves a comparison between memory encodings generated from tasks involving judgments of self and those from tasks involving judgments of others. If it is found that the self-schema and the other schema generate similar memory encodings, the contention that all personal information (both self- and other-referent) is processed using a common schema system will be supported. If, on the other hand, self- and other information produces different memory encodings, we will have evidence supporting the self as a distinctive cognitive schema. Further, it will be possible to explore the kinds of differences between self- and other information processing, with an eye to formulating a model of how we process information about other people.

The self–other comparison used in the present experiments also speaks to an important methodological point embedded in the Rogers et al. (1977) experiments. These experiments documented the relative strength of self-reference as an encoding device, thereby supporting the analyses indicating that the self is a schema. In these studies, subjects first made a series of ratings of personal adjectives. For example, subjects had to make synonymity judgments for some of the words. Different words were rated as to whether they described the subject. These rating tasks produced memory traces. The strength of the memory trace was assessed using an incidental recall task, after the ratings were completed. Subjects were instructed to remember as many as they could of the words they had rated. The results of these experiments revealed a clear recall superiority for the self-reference rating task. This finding was interpreted as indicating that the self produces strong and elaborate memory traces and in turn was offered as support for the self as a schema.

There is one important weakness in this argument. Self-reference was compared (and found superior) to rating tasks involving

udgments of synonymity, semantic specificity, rhyming quality, and type size. None of these comparison tasks involved making judgments about people. *It is possible that the superior recall for the self-reference task is due to the involvement of a person in the task and that any rating task involving a person would produce superior recall.* This "generalized person hypothesis" suggests that any rating task with an explicit person referent (self or anyone else) enhances incidental recall in this paradigm. If this hypothesis were correct, both the conclusion that the self produces an elaborate memory trace and the formulation of the self as a schema would be questioned.

The present article presents a series of experiments intended to explore the processing of self- and other-referent information using the incidental recall paradigm from Rogers et al. (1977), which derives from Craik and Tulving (1975). The first two experiments explored self–other differences in this paradigm; the later experiments were designed to elaborate the obtained results. The goal of this experimental series was to clarify the nature of self- and other-referent processing of personal data, in an attempt to better understand the cognitive structures involved in processing information about people.

The Present Experiments

The first two experiments were simple attempts to determine if there are incidental recall differences following self- or other-referent rating tasks. However, before the data are presented, it is instructive to consider what kinds of processes may be involved when a person is required to rate whether a given adjective (e.g., jolly) describes another person. These kinds of rating tasks are not foreign to the personality domain, since they are used in the assessment literature (e.g., peer ratings) and person perception research (Schneider, 1973). Our cognitive position persuades us to explore the kinds of processes and structures that may be involved in this task.

The cognitive literature gives a starting point for considering processes involved in rating other people. Several researchers have explored memory traces involved in making various ratings about people, using a photo as the stimulus. For example, subjects may rate either physical qualities of the person (e.g., size of nose) or psychological qualities (e.g., honesty). In a subsequent recognition task, subjects are better able to identify the faces given the psychological (deeper) ratings (Bower & Karlin, 1974). These data indicate that ratings of others that involve psychological qualities tend to create elaborate memory traces, compared to physical (shallow) tasks. The studies are not overly instructive as to what the underlying mechanisms might be during the rating task. The one hint is Bower and Karlin's suggestion that prototypes mediate the judgments of others.

Another area that relates to judgments about others is person perception (e.g., Schneider, 1973; Wiggins, 1973). One finding that consistently emerges in this domain is that the lay perceiver finds it easy to go from behavioral data to inferences about dispositions (Hastorf, Schneider, & Polefka, 1970). In rating another person, the rater is apt to use factors such as appearance, behavior, social relationships, typical contexts, personal origins, and internal properties (Fiske & Cox, in press). The mechanisms involved in making these inferential leaps are usually thought to involve certain classes of conceptual structures that prescribe certain behavior–trait relationships. These structures, sometimes referred to as implicit personality theories, facilitate generation of dispositional inferences.

These two domains of research (rating faces and implicit personality theory) give us some ideas as to how people may make ratings of other people. Presumably, the cognitive structures associated with the person's implicit personality theory form an integral part of this rating process. This being the case, rating another person with respect to psychological characteristics should provide a relatively elaborate (or deep) memory trace. The research involving faces supports this contention. In toto, the data suggest that trait or "deep" ratings of others should enhance incidental recall. The critical ques-

tion is whether this enhancement is comparable to that documented for self-referent judgments in the Rogers et al. (1977) experiments.

Since both the self- and other-referent tasks involve cognitive structures (self and implicit personality theories, respectively), it may be possible that they share some functions as well. It is most likely that both cognitive structures allow us to simplify and reduce the incoming data to a manageable size. Implicit personality theories are thought to allow us to "simplify the complex world of other people" (Hastorf et al., 1970, p. 16), whereas the self-schema represents the "abstracted essence of a person's perception of him or herself," which evolves to "help the person keep track of the vast amounts of self-relevant information encountered over a lifetime" (Rogers et al., 1977, p. 677). Thus, we have two cognitive structures that appear to possess very similar functions. This situation suggests that differentiation between self- and other-referent tasks may be difficult.

The difficulty of separating self- from other-referent tasks prompted the inclusion of several additional measures in the following experiments. Since differences may be subtle, measures of difficulty and confidence in making the various ratings have been included. It is hoped that these measures will provide information about the subject's perception of these tasks and offer some hints as to the nature of self- and other information processing.

Experiment 1: Self–Other Recall Differences Using the Group Method

This first experiment introduced the basic methodology of the incidental recall paradigm and offered initial data speaking to self–other referent task differences. It was followed immediately by a second experiment using a somewhat different methodology.

Method

In all of the following experiments two basic stages were involved. First, subjects made a series of ratings of a set of adjectives. The ratings were varied during this stage and were communicated to the subject by way of a cue question preceding the presentation of the adjective. Following the ratings, the second stage of the experiments involved a free-recall period in which subjects attempted to remember the words they rated.

Materials. The 48 adjectives (40 target adjectives plus 4 recency and 4 primacy buffers) represented a broad set of personality characteristics, chosen from the scale descriptions of the Personality Research Form (Jackson, 1967). The details of selection are presented in Rogers et al. (1977, p. 680).

The rating tasks used are detailed in Table 1. Four task orders were generated to ensure that each adjective was rated under each task. Within each list one quarter of the words were rated under each task. Task order was randomized in blocks of four, such that each rating task was performed once in a block.

Procedure. Data were collected during the first session of an undergraduate psychology class. With the exception of substituting "describes him" for the phonemic cue question, the procedure was identical to that in Experiment 2 of Rogers et al. (1977).

Experimenter. The target for the other-referent ratings was a male psychology graduate student. The experimental session was his first encounter with these subjects, who were students in his statistics lab.

Subjects. Twelve (11 female) undergraduate psychology students served as subjects. Their mean age was 20.2 years.

Results

Recall performance. The recall protocols were scored under the following conditions: (a) The first and last four adjectives presented were not included, since memory for these is probably due to primacy and recency effects; (b) grammatical transformations of the words were scored as wrong; and (c) a proportion correct score was employed to insure that differential numbers of Yes and No ratings were not affecting the recall scores (see Rogers et al., 1977, pp. 683–684, for details and rationale of this proportionality score).

The mean proportions correct as a function of rating task and rating (Yes or No) are presented in Table 1. As can be seen, the self-referent task produced superior recall. This result was verified in an analysis of variance of the data making up these means. The main effect of rating task was significant, $F(3, 33) = 2.98$, $p < .05$, as was the difference between the self- and other-referent tasks ($p < .05$). The post hoc test also revealed that other-referent recall was not

Table 1
Rating Tasks, Mean Adjusted Recall, and Confidence and Difficulty Ratings for Experiment 1

Rating task	Question	Definition	Mean adjusted recall			Mean difficulty rating	Mean confidence rating
			Yes rating	No rating	*M*		
Structural	Long?	Rate whether you feel the word is long or short.	.16[a]	.19	.18	3.08[b]	3.83[c]
Semantic	Specific?	Rate whether you feel the word has a specific meaning or relates to a specific situation.	.16	.13	.15	4.25	3.83
Other-referent	Describes him?	Rate whether you feel the word describes the experimenter.	.09	.27	.18	5.00	2.75
Self-referent	Describes you?	Rate whether you feel the word describes you.	.42	.21	.31	2.00	6.00
		M	.20	.20			

[a] Adjusted recall values can range from 0 to 1.00. A value of 1.00 indicates that all adjectives receiving a particular rating (either yes or no) for a particular task were recalled. A value of 0 indicates that none of these adjectives were recalled.
[b] Difficulty ratings were made on a 7-point scale with endpoints of (1) "not at all difficult" and (7) "extremely difficult."
[c] Confidence ratings were made on a 7-point scale with endpoints of (1) "not at all confident" and (7) "extremely confident."

superior to the semantic task. For the structural, semantic, and self-referent tasks, the pattern of present results replicates exactly the findings of Rogers et al. (1977).

Clustering. One possible explanation of the recall findings is that subjects simply wrote down every adjective they felt was self-descriptive during the recall phase. If they did this, their self-referent recall would appear to be excellent relative to the other tasks. This hypothesis predicts two things. First, there should be a large number of intrusions in the recall protocols. This was not found ($M = .25$ intrusions per subject). Second, if subjects were merely listing the features stored in their self-concepts, all words rated under the self-referent task would be emitted together, or in a definite cluster. The measure of clustering outlined by Dalrymple-Alford (1970) was calculated for the recall protocols to assess this possibility. This measure permits a comparison between the number of repetitions observed in the output and the number expected if the recalled words were emitted randomly. The Dalrymple-Alford measure also adjusts for lengths of protocol and the number of each kind of element observed. Significant deviations between the observed and expected number of repetitions would support the hypothesis that the superior self-referent recall is due to a simple listing of the features comprising the self.

The series analyzed for each subject was the task under which each successive item in the recall protocol was rated. While there was a tendency for there to be more repetitions observed than expected ($M = 3.17$ and 2.61, respectively), these figures never approached statistical significance, $\chi^2(11) = 1.13$, p (sign test) $= .61$, suggesting that output order was close to that expected by chance. This difference remained nonsignificant even when several variations of the Dalrymple-Alford measure were used. To save space, it will be mentioned here that the same results were obtained for all recall data reported in this article, suggesting that there is not a meaningful amount of clustering in the recall data of these experiments. As suggested in Rogers et al. (1977), the incidental recall data appear to reflect more encoding than retrieval processes.

Difficulty and confidence ratings. The means of the postexperimental ratings of the encoding tasks are presented in Table 1. One-way analyses of variance of these ratings revealed significant effects for both the difficulty, $F(3, 33) = 9.04$, $p < .001$, and confidence, $F(3, 33) = 16.22$, $p < .001$ ratings. Post hoc tests revealed that the subjects found the other-referent task significantly more difficult than the self-referent rating ($p < .01$). They also placed a significantly greater degree of confidence in the

self-referent, compared to the other-referent, task ($p < .01$).

Experiment 2: Self–Other Recall Differences Using the Individual Method

Method

Experiment 2 was conducted to extend the generality of the self–other difference found in the first study by incorporating three methodological changes. First, a different other–target was used to ascertain if the target was an important aspect of the ratings. Second, the semantic rating task was changed to a synonymity rating. Third, subjects were tested individually, which permitted assessment of the time required to make the ratings (RT). The procedures outlined in Rogers et al. (1977, Experiment 1) were used. The only change was that the rhythmic task was replaced with an other-referent task.

Materials. The adjectives from Experiment 1 were used. The necessary synonym list for the new semantic task was taken from Experiment 1 of Rogers et al. (1977).

Procedure. All of the stimuli were presented on a television monitor driven by a PDP8/1 computer, which also recorded the ratings (yes or no) and rating times (in msec). Each of the 48 trials consisted of (a) a 3-sec presentation of the cue question, (b) a ½-sec blank interval, (c) presentation of the adjective, (d) a response by the subject that terminated the visual display, and (e) a 2-sec intertrial interval. Following the 48 trials the subject was allowed 3 min to recall, in any order, as many of the words as he or she could.

Experimenter. The rating target for the other-referent condition was a female psychology graduate student, who was unknown to the subjects. The only contact between her and a given subject was a telephone call asking for the subject's participation and the 5-min period before the experiment began, which was filled with greetings and instructions.

Subjects. The 24 volunteers (14 females) who took part were students in introductory psychology courses. Their mean age was 18.5 years, and each was paid $2 for his or her participation. They were randomly assigned to one of the eight lists.

Results

Recall performance. The mean proportion of items recalled as a function of rating task and rating is presented in the upper panel of Table 2. As can be seen, the self-referent task produced superior recall, followed by the other-referent encoding task. As in Rogers et al. (1977), the structural task produced the poorest recall. An analysis of variance of these recall data revealed a main effect of rating task, $F(3, 69) = 15.67$, $p < .001$, replicating Experiment 1. However, a fine-grained analysis of this main effect revealed that the self- and other-referent recall difference did not reach statistical significance.

Response time. RT was defined as the time from the onset of the adjective on the monitor until the subject pressed the button revealing a Yes or No response. These RTs were calculated separately for each rating task for each rating (yes or no); the means are presented in the second panel of Table 2. A two-way analysis of variance of the data involved in these means revealed a single meaningful main effect of rating task, $F(3, 69) = 27.05$, $p < .001$.

The focal concern of this study is the memory trace laid down by the rating tasks. When considering RTs for *all* ratings, we are dealing with nonrecalled words as well as recalled ones. Since nonrecalled words generated nonfunctional traces, the overall RTs do not speak directly to the issue of useful memory traces. Because of this, mean RT was analyzed as a function of whether a word was recalled. For the two person tasks, the mean RT for recalled and nonrecalled words was calculated, and the means are entered in the third panel of Table 2.[1] The critical observation of these data is the 848-msec difference between the two rating tasks for recalled words. Analysis of variance of the 2×2 matrices ($n = 23$) revealed a main effect of rating task, $F(1, 22) = 12.02$, $p < .01$, and an interaction, $F(1, 22) = 4.42$, $p < .05$. Post hoc tests revealed that for the other-referent task, the recalled words had meaningfully higher RTs than the nonrecalled words. Further, considering only the recalled words, the self-referent task produced significantly shorter RTs than the other-referent task. All other comparisons were nonsignificant.

Confidence and difficulty ratings. As can

[1] It was not possible to fill sufficient cells for this analysis if the rating (yes or no) variable was retained, hence it was not included. One subject was eliminated from this analysis because of an empty cell.

be seen from the lower panel of Table 2, the confidence and difficulty ratings replicate those shown in Table 1. Analysis of variance of the confidence rating means revealed a significant effect of rating task, $F(3, 69) = 25.29$, $p < .001$, with post hoc tests revealing significance for the self/other-referent comparison ($p < .01$). For the difficulty ratings the self/other comparison of the significant main effect of rating task, $F(3, 69) = 54.73$, $p < .001$, revealed that the other-referent task was rated as significantly ($p < .01$) more difficult to perform than the self-referent judgment.

Discussion

The results of these two experiments indicate that (a) more adjectives rated under the self-reference task were remembered compared to the remaining encoding tasks; (b) clustering analyses revealed no unusual patterning in the recall protocols; (c) RT for encoding interacted with rating task and recall of words; and (d) difficulty and confidence ratings indicated that self-reference judgments were easier and were made more confidently than the other-referent judgments. These results, found using two different methods, paint an interesting picture of the differences between the self- and other-referent rating tasks.

First, the recall data suggest that the "general person hypothesis" is not tenable. In Experiment 1 an encoding task involving another person did not produce recall equivalent to the self-reference task. This finding suggests that it is not simply the involvement of a person per se in the encoding rating that facilitated recall. Rather, the superior self-reference recall documented here and in Rogers et al. (1977) is the result of the self being active during the encoding task. Experiment 2 showed a similar pattern of results, but fine-grained analysis revealed that the self- and other-referent recall were

Table 2
Summary of Results for Experiment 2

Measure	Rating task				*M*
	Structural	Semantic	Other-referent	Self-referent	
Mean proportion correct recall					
Yes rating	.09[b]	.20	.26	.35	.23
No rating	.07	.12	.25	.30	.19
M	.08	.16	.26	.33	
Overall mean RT[a] (in msec)					
Yes rating	1,280	2,639	2,855	2,536	2,327
No rating	1,449	2,632	2,837	2,674	2,398
M	1,364	2,635	2,846	2,605	
Mean RT[a] for selected subjects ($n = 23$)					
Recalled words			3,223	2,375	2,799
Nonrecalled words			2,714	2,558	2,636
M			2,968	2,466	
Mean difficulty rating	1.33[c]	3.20	5.66	2.83	
Mean confidence rating	6.45[d]	4.83	2.79	5.37	

[a] RT = response time.
[b] Adjusted recall values can range from 0 to 1.00. A value of 1.00 indicates that all adjectives receiving a particular rating (either yes or no) for a particular task were recalled. A value of 0 indicates that none of these adjectives were recalled.
[c] Difficulty ratings were made on a 7-point scale with endpoints of (1) "not at all difficult" and (7) "Extremely difficult."
[d] Confidence ratings were made on a 7-point scale with endpoints of (1) "not at all confident" and (7) "extremely confident."

not significantly different. This result could be due to any number of factors relating to the different methods employed (e.g., the group method is experimenter paced, whereas the individual method is self-paced). This failure to find self–other differences could be damaging for our self theory, were it not for the consistent pattern of results emerging from the other dependent measures, particularly the RT and rating data.

The major difference between the self- and other-referent tasks was that words recalled under the other-referent task were those upon which the subject expended a large amount of effort, as witnessed by the inflated RTs ($M = 3{,}223$ msec). When effort was not expended during the other-referent rating, the word tended to not be recalled ($M = 2{,}714$ msec). The opposite pattern of results was obtained for the self-rating task, with recalled words showing faster RTs ($M = 2{,}375$ msec) compared to those that were not recalled ($M = 2{,}558$ msec). Thus, recall under the other-referent condition is "effort tied," whereas self-reference recall is not. The finding that subjects found the self-referent task easier and placed more confidence in their self-ratings compared to the other-referent task underscores the differences between these two encoding tasks. Overall, these results indicate that the self- and other-referent tasks involve two different types of cognitive processes.

The other-referent task can be characterized as a rehearsal or frequency type of process. Here, if the subject works hard during encoding (e.g., rehearses or repeats the adjective), he or she is apt to recall the item. The absence of this effort during encoding predicts poor recall. This type of process is reminiscent of verbal learning frequency theory (e.g., Klatzky, 1975) in that there is a simple linear relationship between RT and recall. The effort during encoding could be sheer rote repetition (though this is unlikely) or related to trying to "pigeonhole" or form an impression of the target person. This process may involve some kind of a schema or prototype, albeit a somewhat weak one. Subjects clearly indicated they were not confident of their other-referent ratings and found them difficult to make, which reinforces this rehearsal-type interpretation.

The data suggest a very different process for the self-referent ratings. The recalled words do not show inflated RTs during the ratings. Rather, there is even a hint that the words that were easiest to rate are those that were recalled. This suggests that words that were easily integrated into the self-schema were those that were recalled. The finding that subjects found the self-referent task easy and had confidence in their ratings supports this interpretation. It appears that the self-referent task is based on an efficient schema. Presumably, the adjective is compared to the self-concept as it is rated (see Rogers, 1974), and the appropriate response is generated. This involvement of the self produces a rich and functional memory trace, which facilitates recall. The present data do not permit precise inferences about how the self-ratings are actually performed. However, the results indicate that these ratings involve the use of a highly organized and efficient self-schema and that the process involved is very different from the other-referent rating.

These data, then, suggest a "two-process" interpretation of self–other differences in processing information. Data about others are processed using a frequency of rehearsal process, whereas self-referent data involve the use of a highly organized cognitive schema.

Experiment 3: A Closer Look at the Process Differences

Despite the relatively strong support for the two-process interpretation of self- and other-referent tasks provided by the first two experiments, several weaknesses remain. First, it is a post hoc explanation and thereby demands independent testing. Second, it was not possible to analyze the RT data of Experiment 2 for the effects of rating (yes or no). Third, lack of sufficient observations forced elimination of one subject in the previous experiment, which attenuates generalizability. Experiment 3 was designed to overcome these problems by (a) providing a direct test of the two-process interpretation, (b) ensuring a sufficient number of ratings

to permit assessment of yes/no variations, and (c) increasing the number of ratings per task to eliminate any possibility of empty cells in the subject data matrices. In order to fulfill (b) and (c) without making the overall task unmanageable, the structural and semantic tasks were eliminated, thereby doubling the number of self- and other-referent ratings to 20 per task. A further change was the use of yet a third target for the other-referent task.

Predictions in this study relate to the two-process interpretation presented above. If the other-referent task involves frequency or rehearsal processes *and* the self-referent rating is based on an efficient schema, RTs should be greater for the other-referent task. Furthermore, this effect should be stronger for recalled words, predicting an interaction between rating task and recall (recalled and nonrecalled words). It is even possible that the effect would emerge as a three-way interaction when the rating (yes or no) variable is added.

Method

All aspects of this study were identical to Experiment 2 except that only self- and other-referent tasks were used. This meant that only two stimulus orders were necessary to counterbalance adjectives across rating tasks.

Experimenter. A female psychology graduate student ran the subjects and served as the target for the other-referent ratings. She was not the same experimenter used in Experiment 2.

Subjects. Twelve undergraduate volunteers (six female) served as subjects. Each was paid $1.50 for participating. Their mean age was 20.3 years.

Results and Discussion

The adjusted recall as a function of rating task and rating was calculated. The other-referent recall ($M = .23$) was less than the self-referent recall ($M = .28$), replicating the previous experiments. However, as with Experiment 2, this difference was not significant, $F(1, 11) = 1.01$. Furthermore, the remaining terms in the adjusted recall analysis of variance were also nonsignificant.

The mean times required to make the self- and other-referent ratings were calculated for each subject. A t test on these data revealed that other-referent ratings required significantly more time ($M = 3{,}784$ msec) than did the self-referent ($M = 3{,}191$ msec) ratings, $t(11) = 2.98$, $p < .01$. This pattern of results also replicates Experiment 2 and offers preliminary support for the two-process interpretation.

Table 3
Mean Reaction Time (in msec) as a Function of Rating Task, Recall, and Rating for Experiment 3

Rating	Rating task: Other-referent	Rating task: Self-referent	*M*
Recalled words			
Yes	5,133	2,936	4,035
No	4,054	5,124	4,589
M	4,594	4,030	4,312
Nonrecalled words			
Yes	3,461	3,119	3,290
No	3,843	3,488	3,666
M	3,652	3,304	3,478

Note. $n = 12$.

The important analysis in this experiment involves RTs as a function of rating task, recall, and rating. Such a matrix was calculated for each subject; the overall means based on all subjects are presented in Table 3. The noteworthy aspect of these means is the evident "crossover" of RTs in relation to rating and rating task *for the recalled words only*. This crossover emerges statistically as a significant three-way interaction, $F(1, 11) = 6.77$, $p < .025$, in the analysis of variance conducted on these data. Other significant terms in this analysis were (a) the main effect of recall, $F(1, 11) = 21.34$, $p < .001$, indicating that RTs were higher for recalled words, and (b) the Rating Task × Rating interaction, $F(1, 11) = 8.50$, $p < .025$, which is clearly qualified by the triple interaction. The main effect of rating task was not significant.[2]

[2] This finding may appear incongruous with the earlier "overall RT" analysis, but it is not. The categorization procedure used to derive the eight mean RTs per subject weighs the raw RTs unequally. The overall RT analysis assigned an equal weight to each raw observation.

These data indicate that the Yes-rated RTs neatly replicate the pattern of results observed in Experiment 2 (Table 2). These data are a second verification of the two-process interpretation, wherein it appears that the self- and other-referent tasks involve schema-based and rehearsal-based processes, respectively.

The words receiving No ratings paint an almost opposite picture to the Yes-rated adjective. The longest RT in the No condition was for recalled self-referent words (5,124 msec), which was the shortest RT for Yes words (2,936 msec). However, post hoc tests failed to reveal any significant differences within the No words, which suggests that the Yes-rated words carried the useful information for differentiating other- and self-referent processing. This result reinforces the conclusions in Rogers et al. (1977), where emphasis was placed on the Yes-rated words in their schema interpretation.

Experiment 4: Familiarity of the Other-Target

The three studies reported above were concerned with an unfamiliar other. Care was taken to ensure a minimum of contact between the subjects and the other-referent target. This was done to minimize possible confounds in the designs associated with how well the subjects knew the other-target. However, it is possible that familiarity is an important aspect of other-referent ratings, and as such deserves systematic investigation. Experiments 4 and 5 considered this possibility, using the same paradigm as the previous studies.

There are some hints in the literature that familiarity does affect processing of information about others. Koltuv (1962) observed a simpler multivariate structure for judgments of an unfamiliar other, compared to known targets. This led Hastorf et al. (1970) to suggest the following:

> Implicit theories of personality in the form of assumptions about which traits are related to one another operate most strongly when the perceiver faces an ambiguous person, one he does not know well. On the other hand, when the perceiver is rating people he knows something about, such stereotyped inferences are modified to fit actual characteristics of the other more closely. (p. 44)

There is also evidence to suggest that degree of acquaintance has a powerful effect on the validity of trait inferences (Norman & Goldberg, 1966). Willingness to ascribe a trait to a person has been found to decrease with familiarity (Nisbett, Caputo, Legant, & Marecek, 1973). Each of these studies suggests that familiarity with the other is a salient attribute of how we process personal information.

The ratings of an unfamiliar other in the first three studies of the present article were probably based on a stereotype or expectancy of the psychology graduate student who served as the target (Jones & Gerard, 1967). During this time the subjects were trying to develop a cognitive structure for the target, but the lack of available information forced recourse to a stereotype (Secord & Backman, 1974). This suggests that effort in making the judgment is likely to be an important variable, which was reflected in the RT analyses. However, as familiarity increases, two critical elements change. First, there is more information available, and second, there is more time to formulate a cognitive organization or structure for that person. These two factors should lead to a reasonably accurate and organized cognitive structure as familiarity increases (e.g., Hastorf et al., 1970). Other-referent decisions should then be based on this new organization and produce reasonably elaborate memory encodings. Furthermore, during the recall phase, this organization can become part of the retrieval environment and thereby facilitate recall. All of this suggests that other-referent ratings for a familiar person should produce excellent recall in the incidental recall paradigm.

Method

Experiment 4 was an exact replication of Experiment 1, involving the same subjects and the same experimenter/other-target. The only difference was that the experiment was run 11 weeks after Experiment 1. During this period the experimenter became more familiar to the subjects, since he was their lab instructor in the course. One feature added after the recall period was the collection of several familiarity ratings.

Results and Discussion

The familiarity ratings indicated that the subjects felt they knew the experimenter "moderately well" and a little less than a "casual acquaintance." Almost all subjects indicated that their interaction with the experimenter had been limited to the classroom and the instructor's office.

The adjusted recall figures, the means of which are presented in Table 4, were subjected to an analysis of variance with rating tasks and ratings as factors. The only significant effect was the main effect of rating task, $F(3, 33) = 4.23$, $p < .025$. Post hoc tests failed to reveal a self-referent–other-referent difference, but recall for both person tasks was superior to that of the semantic task.

The difficulty ratings showed a pattern of significance similar to that of Experiment 1, $F(3, 33) = 7.09$, $p < .001$, with the self-referent judgments being rated as significantly easier than the other-referent judgments ($p < .05$). The confidence ratings also replicated those of Experiment 1, $F(3, 33) = 14.96$, $p < .001$, with the self-referent judgments receiving significantly higher confidence ratings ($p < .05$) than all of the remaining tasks.

These data confirm the predictions deriving from a view that suggests that familiarity results in the development of an accurate organization. The enhanced recall under the other-referent rating ($M = .18$ in Experiment 1 and .40 in Experiment 4) appears to be due, in part, to the increased familiarity with the other-target, derived from 11 weeks of experience with him. The self-referent recall is roughly the same for the two experiments (Ms $= .31$ and .32, respectively). Hence, the effect of familiarity is to dramatically enhance incidental recall for words rated under an other-referent task. This result suggests the development of a cognitive structure for the now-familiar other.

Table 4
Mean Adjusted Recall and Confidence and Difficulty Ratings for Experiments 4 and 5

Rating	Rating task: Structural	Semantic	Other-Referent	Self-Referent	*M*
		Experiment 4 ($n = 12$)			
Mean adjusted recall					
Yes	.10[a]	.24	.30	.35	.24
No	.22	.29	.50	.27	.32
M	.16	.26	.40	.32	
Mean difficulty	3.66[b]	4.66	3.83	2.16	
Mean confidence	3.42[c]	3.00	3.16	6.00	
		Experiment 5 ($n = 15$)			
Mean adjusted recall					
Yes	.09	.20	.37	.39	.26
No	.17	.07	.28	.29	.20
M	.13	.13	.32	.34	
Mean difficulty	3.20	4.53	4.60	1.60	
Mean confidence	3.66	3.53	3.06	6.13	

[a] Adjusted recall values can range from 0 to 1.00. A value of 1.00 indicates that all adjectives receiving a particular rating (either yes or no) for a particular task were recalled. A value of 0 indicates that none of these adjectives were recalled.

[b] Difficulty ratings were made on a 7-point scale with endpoints of (1) "not at all difficult" and (7) "extremely difficult."

[c] Confidence ratings were made on a 7-point scale with endpoints of (1) "not at all confident" and (7) "extremely confident."

Experiment 5: Intentional Versus Incidental Recall

The repeated experimental design employed in Experiments 1 and 4 brings one obvious problem with it. Since subjects had been tested previously in the same situation, possibly the observed effects of Experiment 4 were due to a sensitizing effect (see Campbell & Stanley, 1967, p. 18). The second study (Experiment 4) represented an intentional learning situation, whereas Experiment 1 was an incidental paradigm. An examination of the cognitive literature (Postman, 1964) indicates that an intentional/incidental manipulation may, under certain circumstances, affect subsequent recall levels. To rectify this, a second group of subjects was run. These subjects were in the same course as the previous subjects, but in a different lab section. The same experimenter was the lab instructor for this section. When tested at the same time of year as the subjects in Experiment 4, these subjects had an equivalent degree of familiarity with the experimenter—but had not been sensitized with a pretest. If the results of Experiment 4 are replicated, the sensitizing effect will be ruled out as an alternate explanation.

Method

The same procedures and materials employed in Experiment 4 were used in this study. Subjects were 15 students (3 male) in an undergraduate psychology course, with a mean age of 19.8 years. They were run during a lab session.

Results and Discussion

The familiarity ratings of this group were the same as those found for Experiment 4. The data from this experiment are summarized in Table 4. The analyses of these data revealed the same pattern as observed with Experiment 4: (a) a main effect of rating task, $F(3, 42) = 9.89$, $p < .001$; (b) equivalent levels of recall for both the self- and other-referent tasks; (c) significant recall differences between the two person tasks and the semantic judgment; and (d) significantly lower confidence ($p < .01$) and higher difficulty ($p < .01$) ratings for the other-referent task compared to the self-reference condition. The major impact of these findings is that they permit rejection of a sensitizing effect as an explanation of the data in Experiment 4.

Taken in combination, the results from Experiments 4 and 5 suggest that familiarity with a person tends to enhance the probability of generating an elaborate and functional memory trace in the incidental recall paradigm. It appears that familiarity aids in the development of a cognitive structure that can be used to process information about that person. Presumably, this structure becomes more elaborate and embellished with increased familiarity.

General Discussion

The data from the five experiments construct a consistent argument for several propositions regarding the processing of information about people. The experiments leave little doubt that the processes attending other- and self-referent decisions are different. This difference is reflected in the consistent differences in RTs observed in Experiments 2 and 3. Not only did other-referent decisions require more time than self-referent ratings, but the RTs also showed some interesting interactions with the various independent variables. Of particular interest is the finding that words recalled from the other-referent condition were those requiring a greater amount of time for the rating to be performed. All five experiments revealed consistent patterns in the confidence and difficulty ratings, indicating that self-referent decisions were easier and produced more confidence in the given response. Within the constraints of the RT findings and the ratings data, the recall results from the five studies also support the contention that self- and other-referent decisions represent different processes. This two-process interpretation has a number of implications for the study of processing personal information.

The Self as a Cognitive Schema

First, the pattern of results supports the proposition that the self functions like a

schema. In all five studies, words receiving Yes ratings under the self-referent conditions were better recalled than No-rated words. This finding suggests that self-descriptive words, presumably those that "fit" with the self, produce strong and elaborate memory traces.[3] Such results would be expected if a schema is the basis of the self-referent decision.

Another aspect of the present data supports the self-as-schema view. Not only were self-referent decisions faster than other-referent judgments but they also showed an opposite pattern in regard to which adjectives were recalled. In the other-referent task, words with long RTs were recalled, whereas with the self-referent task, there is a hint that words with short RTs—presumably those that "fit" with the self—were those that were recalled. Again, a view that suggests the self is a schema predicts this pattern of results. When these two pieces of supporting evidence are combined with published data, an impressive case for the schema property of the self can be made. Some of this convergent evidence includes the following: (a) Greater amounts of information are available for terms in the self-concept, which is to be expected from a schema (Markus, 1977); (b) resistance to incorrect personal feedback is related to the degree of self-description (Markus, 1977), which demonstrates the activity of the self-schema during the processing of new information; and (c) several biases documented in recognition memory mirror those found for experimentally manipulated schemata (Rogers et al., in press).

All of this evidence suggests that the self is an important agent in the processing of personal information. Each of these lines of evidence can be predicted from a position that defines the self as an abstract cognitive structure that contains both general trait-like entries and some specific behavioral exemplars or instances. This memory structure is active during the input and interpretation of self-related information and provides a degree of "meaning" or embellishment to the incoming information. The self can be seen to act as a hook or interpretative frame for the encoding of personal data. The clustering analysis of the present data clearly indicate that the self is active during encoding. If the data were a retrieval phenomenon or simply reflected a listing of self-referent features, some degree of clustering in the output protocols should have been observed. Since this was not found, the present data reinforce the proposition that the self is a powerful agent during the encoding of personal information.

Processing Information About Unknown Others

A second aspect of the present data is the information they provide us about how we rate other people. The results for the other-referent conditions in the current experiments provide several suggestions about the mechanisms involved in making decisions about the psychological characteristics of another person. Ratings of an unfamiliar other person appear to involve a relatively inefficient frequency type of process, with the memory trace relating to the amount of effort that the rater puts into his or her response. This effort probably relates to attempting to form an impression of the other person. Secord and Backman (1974) suggest that the context, the target, *and* the observer contribute to the initial view of an unfamiliar other. People do use *contextual information* in forming impressions (e.g., Price, 1974). This fact sometimes emerges in the form of the context determining what information about a person is salient for a given situation. The *target person* elicits a considerable number of cues, even in a short exposure. Several researchers have provided categories of the kinds of information that might be involved (Beach & Wertheimer, 1961; Secord & Backman, 1974). Fiske and Cox (in press) suggest the following categories: (a) traits, (b) demographic parameters (e.g., race, sex), (c) spe-

---

[3] As indicated in Rogers et al. (1977), this difference fails to reach significance in individual studies. However, when we combine the previous research with the present five studies, we have nine separate verifications of Yes-rated words showing significantly better recall than No-rated words in the self-reference task, $p = 1/512 = .002$.

cific behaviors (e.g., verbal output *and* nonverbal cues—see Secord & Backman, 1974, p. 43), and (d) appearance (e.g., Jones & Gerard, 1967).

A third source of information about an unfamiliar other is the *observer*. Here we encounter implicit personality theories and stereotypes that prescribe various expectations or predictions about another person (e.g., Hastorf et al., 1970). These allow us to "fill in the holes" left by an inadequate opportunity to observe the target and thereby to embellish an incomplete memory representation. The observer's self may also be involved in the rating of another person. The possibilities here range from making relativistic appraisals of the other person (e.g., "He's more aggressive than I am—hence, he's really aggressive") to the imposition or projection of self-referent characteristics onto the other person (e.g., Koltuv's 1962 projectivist hypothesis). The increased availability of behavioral exemplars for self-descriptive qualities (Markus, 1977) suggests that such qualities may be used more often in judging other people.

All of these sources of information no doubt combine in subtle and complex ways to produce the subjects' ratings, and indeed the domain of person perception addresses these kinds of issues (Tagiuri, 1969). Although the present data do not permit statements about how these sources may combine, they do clearly indicate that the memory trace for the rating event is very different from that created during a self-referent rating. The other-referent data show that increased time performing the rating—which could be due to either seeking out additional information or combining available inputs—enhances the probability of subsequent recall. This finding suggests a frequency or strength model, in which increased input makes increments in some internal memory store and thereby facilitates subsequent performance.

Familiarity and a Model for Other Processing

A third proposition about the processing of personal information comes from manipulating the familiarity of the target for the other-referent rating. Apparently, familiarity with the target significantly modifies the processes involved in the judgment. Memory performance is enhanced after the subject comes to know the target (Experiments 4 and 5). This enhancement suggests that familiarity with the target permits a more efficient cognitive system for representing the other person than was available in the case of an unfamiliar target. The present data do not permit statements about whether these ratings are based on attempts to "type" a person (Cantor & Mischel, 1977), implicit personality theories (Schneider, 1973), or some form of self-involvement in the processing of information about others (Lemon & Warren, 1974). Rather, they do tell us that there are substantial changes in the cognitive system as we come to know a person better.

These changes relate to the increasing information we acquire about another person with increased familiarity. At some point during the accumulation of information about another person, an overload state must be encountered. That is, there must be a time when we can no longer keep track of all of the actually observed information we have about that other person. In order to cope with this, either the cognitive structure must change or we will have to ignore new information. If the cognitive structure changes, it probably shows an increasing degree of abstraction in content. Rather than remembering a series of specific instances, a general statement representing the commonality of the other's behaviors may be the stored element. To be certain, specific instances can be generated from this general statement, but the stored element is the generalization about the other person's behavior. Fiske and Cox (in press) present evidence consistent with this proposed interpretation. When individuals are asked to describe an unknown other (stranger), they rely heavily on specific behavioral exemplars or scripts, rather than abstracted traits. However, when asked to describe a known other, subjects generate descriptive protocols that indicate a higher frequency of abstracted traits than of specific observed behavior. Furthermore, traits are generated much earlier in the protocols for known others, suggesting that they do indeed

serve a summarizing function. For strangers, traits begin to emerge in the protocol only after the opportunity for observation has been provided. Hence, increased exposure to the target enhances the probability of abstraction.

The critical question is, *What guides the abstraction process that allows us to summarize the available information about the other person?* Implicit personality theories, stereotypes, and the kinds of attributes outlined by Fiske and Cox (in press) are no doubt part of this process. However, it is possible that the self is also very active here. The self is a cognitive structure that has evolved to help summarize available self-related information. This means it serves the same function as the abstraction process involved with other people. It is an intriguing possibility that how we summarize information about other people is bound up with our own view of self. Several lines of research evidence are compatible with this suggestion.

Self-Involvement in Other-Processing

First, it appears that the same traits may be used in the perception of other people as are used in self-perception. For example, Lemon and Warren (1974) found that personally relevant traits are used more often and earlier in free descriptions of other people (see also Shrauger & Patterson, 1974). This suggests that the self may shape our views of others.

Second, the research involving self-based consensus implies that people surmise population performance from their own behavior (Heider, 1958). More recently, Ross (1977) has formulated the notion of a "false-consensus bias" in attributions, which suggests that the self serves as a reference point in interpreting information about others. Briefly, the false-consensus bias postulates that laymen see their *own* behavioral choices and judgments as relatively common and appropriate to existing circumstances, while viewing alternate responses as uncommon, deviant, and inappropriate (Ross, 1977). An important corollary of this hypothesis is that a person judges those responses that differ from his or her *own* to be more revealing of another's stable disposition than responses that are similar (Ross, 1977). To the extent that persons use their own views to interpret information about others, the self is probably involved in processing information about others.

A third line of research and theory that speaks to the issue of the self being involved in the ratings of other people emerges under the idea that the self functions like a fixed cognitive reference point. Snygg and Combs (1959) suggested that the self is *the* reference point for the processing of *all* information. With respect to the processing of information about others, they suggested that "people are not really fat, unless they are fatter than we are" (Snygg & Combs, 1959, p. 145). Comparisons of others to the self also form the keystone of Festinger's (1954) "social comparison" theory and Jones and Gerard's (1967) "comparative appraisal" theory of self-development. Lemon and Warren (1974) and Shrauger and Patterson (1974) offer empirical evidence consistent with this notion of an implicit and automatic self–other comparison being an integral part of how we process information about other people.

These three lines of research are compatible with the notion that the self, as a cognitive structure, is involved in the processing of information about other people. This idea does not imply that the content of a cognitive structure for another person is the same as the content for the self. Rather, it suggests that the self is involved in the development of the cognitive representation of another person. The manner in which the self helps shape this development and the kinds of biases that may emerge are fodder for a considerable amount of future research. For the present, it appears that there may be a complex involvement of the self in the processing of information about other people.

In summary, the present data do verify that self- and other-referent tasks are performed using different processes when the target other is unfamiliar. There is also an indication that the cognitive structure associated with another person undergoes some substantive changes as familiarity increases.

However, these findings relate to only one kind of decision about other people and, as such, beg for further research to explore their generality. We hope that this research will be hardheaded experimental work that begins to shed light on the developmental sequence of the cognitive structures involved in processing information about other people.

Making Trust Easier and Harder Through Two Forms of Sequential Interaction

Philip Brickman, Lawrence J. Becker, and Sidney Castle
Northwestern University

If people in a trust dilemma take turns choosing first and second (alternating interaction), there is no longer a dilemma for the people choosing second. Their motives are completely revealed by their choices. In most real-world situations, however, although choices are sequential, each choice is both a response to another person's past move and a stimulus for the other person's next move (continuing interaction). It was hypothesized that cooperation would be harder to achieve in continuing interaction than in alternating interaction, since in continuing interaction, like simultaneous interaction, people's motives are ambiguous. Since males have been shown to be more concerned with communication in trust dilemmas, it was also hypothesized that alternating interaction would benefit males more than females. Data from two studies using a total of 42 male and 42 female dyads supported this reasoning. Thus, we can relax one of the most artificial constraints of the formal trust dilemma—simultaneous choice—and still retain its important psychological properties.

It is enormously important to understand when people will trust each other and when they will not. Experimental social psychology has invested great energy in studying this problem through what are called trust dilemmas or Prisoner's Dilemmas (see Wrightsman, O'Connor, & Baker, 1972, for an extensive review of this literature). In a trust dilemma each person is much better off competing if the other person cooperates (because one exploits the other person's generosity) and is also better off competing if the other person competes (because one defends oneself against exploitation by the other person). Thus, regardless of what the other person does, competing is always a more profitable choice. However—and this is the dilemma—both parties will be worse off if they each compete than they would be if they could both trust each other and cooperate.

The question is increasingly raised, however, as to whether people decide to trust someone else in laboratory experiments on the same basis that they do outside the laboratory (see Wrightsman, O'Connor, & Baker, 1972, also for a discussion of these issues). The present studies address themselves to one possible issue in this debate. In laboratory experiments on trust dilemmas, both parties to the dilemma are usually asked to decide whether to trust each other simultaneously and in ignorance of each other's choice. Mutual simultaneous choice is necessary for a situation to be considered a formal trust dilemma (Rapoport & Chammah, 1965a). However, in social interaction situations outside the laboratory, people rarely make choices that are precisely simultaneous and continue to be so over an extended period of time. Social interaction ordinarily consists of a sequence of events in which each party's action in turn stimulates subsequent action by the other party. If making choices in sequence removes the logical and psychological dilemma in trusting, the dynamic of the trust

The authors wish to thank Darwyn E. Linder for the helpful comments he made in a review of an earlier draft of this article.

dilemma is applicable only to a very narrow and special set of circumstances.

We wish to demonstrate that there are two forms of sequential interaction. One of them removes the dilemma, to the extent that the dilemma exists because there is ambiguity in deciding why someone has chosen not to cooperate. The other form, however, continues to make it difficult to decide whether people are interested in exploitation or only in protecting themselves and is also a much more reasonable analogue to ordinary social interaction than either of the other two conditions we will be considering.

Ambiguity of Simultaneous Choice

Although choosing to compete is always more profitable in a trust dilemma than choosing to cooperate, the motivation for choosing to compete may be quite different depending upon whether the other party is expected to cooperate (in which case competing is a matter of exploitation) or expected to compete (in which case competing is a matter of self-defense). If one knows only that someone has chosen to compete, it is impossible to know whether his or her motivation was exploitation or self-defense. In a situation where both people are choosing simultaneously, it will be impossible to know with certainty whether a person is competing to gain advantage or to protect him- or herself. Kelley and Stahelski (1970b) have mapped out some of the problems that occur because people make different assumptions about what others will do, and McClintock (1972) has developed a sophisticated analysis of the different social motives potentially operative in trust dilemmas.

Clarity of Alternating First and Second Choices

The ambiguity involved in choosing to compete is fully removed if the person competing has already been informed whether the other party is competing or cooperating. If the other party is cooperating, the only reason to compete would be a desire to exploit. If the other party is competing, a desire to defend oneself is sufficient motivation to compete. Conversely, if the other party is competing, the only reason for cooperating in the second position would be a desire to create trust. There is no dilemma for a person choosing second in a sequential choice situation, and there is little difficulty in inferring the motives of a person in this position (cf. Kelley & Stahelski, 1970a). If people choose sequentially rather than simultaneously and take turns choosing first and second, each person should have a variety of occasions on which to signal the other person without ambiguity as to whether he or she is interested in exploitation, or only in self-defense, or actually in creating trust. If people compete in trust dilemmas in part merely because they cannot send or receive unambiguous messages of cooperative intent (cf. Deutsch, 1958, 1960) or because ambiguity serves as a smoke screen that makes it easier to get away with being exploitative, an interaction in which they alternate choosing first and choosing second should produce a greater degree of cooperation than a situation in which both parties choose simultaneously.

Direct tests of this hypothesis so far have yielded ambiguous results. Swinth (1967) found a trend toward more cooperation following an alternating-choice situation, but Wrightsman, Bruininks, Lucker, & O'Connor (1972) found no effect. Deutsch (1958, 1960) found more cooperation in simultaneous play, but he did not have parties alternate choosing first and choosing second. Oskamp (1974) also did not have parties alternate first choices. He, too, found more cooperation in simultaneous play, but only when the payoff matrix had a positive average expected payoff. When the average expected payoff was zero, there was more cooperation in sequential play.

Ambiguity of Continuing Interaction

Knowing whether the other person has just decided to compete or cooperate, however, may not remove the dilemma from one's decision of whether in turn to compete or cooperate. In ordinary social intercourse, every action is both a response to a previous action by the other party and a stimulus to a subsequent action by the other party. As a re-

sponse, the action of competing or cooperating may be taken as a second choice in a trust dilemma, fixing at that moment how much reward each party gets as a function of their joint current orientations toward competing and cooperating. As a stimulus, the action of competing or cooperating may be taken as a first choice in a trust dilemma, setting the stage for the other person to determine by his or her subsequent choice how much reward each party gets as a function of their current orientations.

In what may be called continuing interaction, since each move is both a first move (a stimulus) and a second move (a response), there is no longer a pure second move, and one can no longer infer unambiguously whether a person competes out of a bold desire to exploit or a cautious desire to protect him- or herself. Even if the other person has just chosen cooperatively, the subject cannot be sure that this is not a device to induce a cooperative choice that will subsequently be exploited to the net advantage of the other person. A continuing interaction of this sort conveys more information about participants' motives than simultaneous choosing, but less than an alternating situation in which people's moves count only as either first moves or second moves, not both. We would thus expect that the problem of whether to trust someone, as determined by the precision with which that person's motivation to cooperate can be estimated, would be easiest with alternating interaction, harder with continuing interaction, and hardest with simultaneous interaction. The present research is designed to test this analysis.

Sex Differences

Since sex differences have been an almost universal finding for trust dilemmas from the time they were explored by Rapoport and Chammah (1965b), they may be expected in the present research as well. Most past research has found that females are less likely to cooperate in trust dilemmas than are males (cf. Hottes & Kahn, 1974). The reasons for this finding are still somewhat obscure, but a number of provocative analyses (Bedell & Sistrunk, 1973; Conrath, 1972; Hottes & Kahn, 1974; Johnston, Markey, & Messé, 1973) have suggested that females are simply less aware that communicating cooperative intentions is a critical feature of the situation. If this is so, we would expect that the enhanced opportunity to communicate cooperative intentions in the continuing and alternating games would be of more benefit to males than to females.

The design for the present research was a 2×3 factorial using sex of subject and interaction structure (simultaneous, continuing, or alternating) as independent variables. Two studies were carried out. The purpose of Study 2 was to assess the reliability of the findings in Study 1, to remove a potential confound involving sex of experimenter, and to obtain explicit measures of subjects' attributions of intention for various choice sequences in each interaction condition. Since the procedures for the second study were the same as for the first study, except where noted, the two studies will be described together.

Method

Subjects and Experimenters

In Study 1, 20 male and 22 female undergraduates acted as experimenters. Same-sex students were paired off for a total of 10 male and 11 female experimenter teams. Each team of experimenters recruited and ran three pairs of undergraduate volunteers of the same sex as the team, one pair randomly assigned to each of the three experimental conditions. Thus 20 males and 22 females served in each of the three conditions.

In Study 2, six male and four female undergraduates acted as experimenters. Same-sex students were paired off for a total of two male and two female experimenter teams (one of the male teams had four members). Since one of the purposes of Study 2 was to avoid the confounding of subject and experimenter sex that was set up in Study 1, each team of experimenters in Study 2 recruited and ran six pairs of undergraduate volunteers, three male pairs and three female pairs. Each team randomly assigned one pair of each sex to each of three experimental conditions. Thus, eight males and eight females served in each of the three conditions. The order in which conditions were run by each experimenter team in both Study 1 and Study 2 was randomly determined for each team.

Procedure

The experiments were conducted in dormitories and other living units. Subjects were seated in sepa-

rate rooms, with care being taken to conceal each subject's identity from the other. The experimenters were also separated, each taking the responsibility for briefing one of the subjects.

Subjects were told that the study was one of how people made choices in a social situation. Their ability to handle some difficult social situations would be tested by having them play a special game. Evaluations would be based on the number of points each person earned in the game. The better a person handled such situations, the more points he or she would earn.

In the game, subjects were told, each player would have two possible moves, A or B, with the amount a person won or lost in each round depending both on the choice the person made and on the choice the other player made. To facilitate subjects' understanding of the game, they were handed a sheet of paper listing all the possible combinations of moves, along with their associated payoffs. The sheet showed that if both parties chose A, each would earn 10 points. If the subject chose A and the other person chose B, the other person would win 50 points and the subject would lose 50 points. If the subject chose B and the other person chose A, the subject would win 50 points and the other person would lose 50 points. If both parties chose B, each would lose 20 points. Subjects were quizzed to be sure that they understood these rules and were also told that they could keep their copy of the handout showing the various moves and payoffs and refer to it whenever they wished during the game.

At this point subjects were given a tally sheet on which columns were marked for them to record their move, the other person's move, their payoff, and the other person's payoff for each round. The manipulation of the interaction condition was then introduced, with players being instructed how to fill out their tally sheet on each round. To prevent end game effects, subjects were told only that they would play "a fair number" of rounds; they were actually allowed to play 18 rounds. Following play, subjects in Experiment 2 were asked to rate the extent to which they would infer either a desire to exploit or a desire to create trust from various moves made by the other player after their own previous move had been either competitive or cooperative. These ratings were made on scales ranging from 1 for "not at all" to 7 for "very much." Finally, subjects were brought together and allowed to talk about their experiences and to ask questions of the experimenters. The experimenters explained the study, gave subjects a feedback sheet that they could take with them to review at their leisure, and thanked the subjects for their participation.

Manipulation of Interaction Structure

In the simultaneous-choice condition, subjects were asked to write down their move for each round before being informed of the other player's move. After both subjects had made their choices, the experimenters informed each subject of what the other's choice had been.

In the alternating-choice condition, subjects were told that one would choose first and have his or her choice announced to the other, who would then in turn make a choice. Subjects were also told that they would take turns being in the position of moving first and that the person who was to start the game would be chosen by lot. It was suggested that subjects keep track of which player had chosen first on each round by circling on their tally sheet the choice made by the player who chose first.

In the continuing-choice condition, as in the alternating-choice condition, subjects were told that choices would be made in sequence and that it would be determined by lot who would start the game. It was then explained that each choice they made would always count double (except for the person starting the game)—once as the last move in one round and once as the first move in the next round. If the subject were moving last in, say, Round 7, he or she would write down that move once in the appropriate column for Round 7 and then once again directly below this, in the same column, as the move for Round 8. Similarly, when the other player's move for Round 8 was announced, the subject would write it down once as the last move for Round 8 and once again as the first move for Round 9. Again, subjects were asked to keep track of who had chosen first on each round by circling the choice of the player who had gone first. Subjects in all cases were quizzed to be sure that they understood the tally sheet and the sequence of moves before the game itself was started.

Results

Results of Study 1 were analyzed by means of 2×3 analyses of variance using sex of subject and interaction condition as independent variables. Sex of experimenter was added as a factor in the analysis of the choice behavior measures in Study 2. No significant main effect or interactions involving sex of experimenter were found.

The proportion of cooperative choices in a dyad in Study 1 and in Study 2 is shown in Table 1. In both studies there was a significant interaction between sex of subject and interaction condition: $F(2, 57) = 4.24$, $p < .019$, for Study 1, and $F(2, 12) = 4.00$, $p < .047$, for Study 2. In each case an analysis of simple main effects showed that interaction condition had a significant effect only for males: $F(2, 57) = 7.37$, $p < .005$, for Study 1, and $F(2, 12) = 8.43$, $p < .01$, for Study 2. In both studies a Newman-Keuls analysis indicated that males in the alternating condition had a significantly ($\alpha = .05$) higher proportion of cooperative choices in their dyads

than males in the simultaneous and continuing conditions and that between those latter two conditions there was no significant difference.

In Study 1 the proportion of cooperative moves in a dyad, given a cooperative prior move by the other party, was significantly greater for males, $F(1, 56) = 7.00$, $p < .011$. Although the interaction effect was not statistically significant, males in the alternating condition responded to a prior cooperative move by the other party with a much higher proportion of cooperative choices than males in the other two interaction conditions (see Table 2). The significant sex-of-subject effect on this measure was not replicated in Study 2. In neither study were there any significant treatment effects on the proportion of cooperative choices in a dyad given a competitive prior move by the other party.

Using the arc sine transformation suggested by Myers (1972) for proportions did not essentially change any of the results of the analyses of variance reported above.

The data collected in Study 2 on subjects' attributions of either a desire to exploit or a desire to create trust in hypothetical choice sequences are presented in Table 3. As can be seen, when a cooperative choice of their own is followed by a competitive choice by their partner, subjects are much readier to say that their partners want to exploit them in the alternating and continuing conditions than in the simultaneous condition, and especially in the alternating condition, $F(2, 42) = 6.99$, $p < .01$. When a competitive move of their own is followed by a cooperative move by their partner, subjects are much more willing to attribute a desire to create trust to their partner in the alternating condition than in either the simultaneous or the continuing conditions, $F(2, 42) = 3.34$, $p < .05$. When a cooperative move of their own is followed by a cooperative choice by their partner, subjects are also somewhat readier to say that their partners want to create trust in the alternating and continuing conditions than in the simultaneous condition, especially in the alternating condition, $F(2, 42) = 3.18$, $p < .06$. Finally, competition that follows competition is not seen as particularly indicative of a desire to exploit in any of the three conditions. There were no sex differences on these variables and no Sex of Subject × Interaction Condition interactions.

Table 3
Mean Attributions of Intentions to Other Person as a Function of Choice Sequence and Interaction Condition

Choice sequence		Interaction condition		
Own previous choice	Other's next choice	Simultaneous	Continuing	Alternating
Attributed desire to exploit as motive for competing				
Cooperate	Compete	3.00	4.56	5.06
Compete	Compete	2.12	2.50	2.31
Attributed desire to create trust as motive for cooperating				
Compete	Cooperate	3.19	3.63	5.06
Cooperate	Cooperate	4.12	5.12	5.56

Note. $n = 8$ for each interaction condition. All scales range from 1 for "not at all" to 7 for "very much."

Discussion

There are three main conclusions suggested by this research. The first is that trust dilemmas appear to generalize to continuing interactions, in which parties choose in turn but each party's choice counts as both a response to the partner's previous move and a stimulus for the partner's next move. The rational dilemma of whether to trust somebody and the attributional dilemma of how to interpret that person's intentions hold in modified form for continuing interaction as well as for simultaneous interaction, in which both parties choose at the same time in ignorance of each other's current choice. This result has important implications for the generalizability of the findings of laboratory studies of trust dilemmas and for the conduct of future laboratory studies. These studies have typically involved simultaneous interaction. Outside the laboratory, however, interactions are much more likely to be continuing than simultaneous. (Consider, for example, such phenomena as arms races, contract negotiations, courtship, seduction, and contract bridge.) By showing that trust dilemmas are relevant to continuing interactions as well as to simultaneous ones, the present study encourages us to believe that the dynamics of trust dilemmas underlie problems of suspicion and distrust outside the laboratory as well as inside it. Furthermore, by indicating that we can relax one of the most demanding constraints of the formal trust dilemma—simultaneous choice—and still retain many of the dilemma's important psychological properties, the present research opens the door to the use in future laboratory studies of better experimental analogues, namely those involving continuing interaction.

The second conclusion is that at least for males, trust is hard to achieve in part simply because it is hard to make unambiguous inferences about other people's motivations in the ordinary simultaneous-choice trust dilemma. Even if the subject has chosen cooperatively on his or her own previous move, a subsequent competitive move by the other party is not seen as indicating a clear desire to exploit in a simultaneous game (see Table 3). Even if the subject has chosen competitively on his or her own previous move, a subsequent cooperative move by the other party is not seen as indicating a clear desire to establish trust in a simultaneous game. On the other hand, both these inferences are clearly made for second moves in an alternating game, in which the first move is known in advance by the party making the second move. This knowledge proved sufficient to establish a much higher degree of cooperation among males in the alternating game than in the simultaneous game. Male subjects were apparently willing and able to signal their interest in cooperation in an alternating game and to respond cooperatively to such signals given by their partners. Where a disposition to cooperate exists, the present data indicate that we may take a long step toward resolving trust dilemmas merely by altering the structure of choice in a way that makes each party's motivation clear to the other party.

It should be noted that alternating interaction is a clear advantage for cooperation only when the question of inferring another's motives is paramount. This is not the case, for example, in a situation in which two parties unknowingly determine each other's fate, called the "minimal social situation." The main questions for the actors in the

minimal social situation are discovering which choice the other person prefers and communicating to the other person which choice they prefer. Kelley, Thibaut, Radloff, and Mundy (1962) have demonstrated that under these circumstances, a cooperative solution is more likely if the parties choose simultaneously rather than in alternation.

The third conclusion is that the basis for failure to achieve trust in a trust dilemma is to some extent different for males and females. Like males, females made more unequivocal inferences of motivation in an alternating interaction than in a simultaneous one. Unlike males, however, females were not thereby more cooperative under alternating than under simultaneous conditions. It would appear that the testing and communicating of cooperative intentions is a critical factor for males in resolving trust dilemmas, but not for females. This sex difference may account for Wrightsman, Bruininks, Lucker, & O'Connor's (1972) not finding increased cooperation in the alternating condition. They had twice as many female as male subjects and did not include sex of subject as a factor in the design. The puzzle of female distrust is all the greater because in other situations, females are more cooperative and more compassionate than males (Uesugi & Vinacke, 1963; Vinacke, 1959). We suspect that females are not defining compassion as relevant to the standard trust dilemma and that if they were induced to do so, this would be the key to elevating their tendency to cooperate.

Probability of Acceptance in Dating Choice

James Shanteau and Geraldine F. Nagy
Kansas State University

Three experiments examined the influence of probability of acceptance and physical attractiveness on dating choice. In Experiment 1, 15 females made preferential choices between two male dates, each described by a photograph and a statement of the probability of acceptance. Both probability and attractiveness of the date were found to be important in the subjects' judgments. Further, a multiplying rule for the combination of probability of acceptance and attractiveness was supported, in agreement with the subjective expected utility theory of risky decision making. In Experiment 2, the same females made preferential choices between pairs of dates described by photographs alone. The preferences for 11 of the 15 subjects could only be accounted for by using both probability and attractiveness. A multiplicative combination of probability and attractiveness was also found to be predictive of dating choices made by these subjects. Experiment 3 replicated the results of Experiment 2 with a new group of 14 females. This research provides evidence that (a) females are influenced by both probability of acceptance and physical attractiveness in dating choice and (b) they tend to combine probability with attractiveness in a multiplicative fashion.

Two factors have frequently been hypothesized to play an important role in dating choice (e.g., Walster, Aronson, Abrahams, & Rottman, 1966). One factor is the attractiveness of a prospective date, and the other is the perceived probability of being accepted by the date. The importance of attractiveness, particularly the physical appearance of the date, has been repeatedly demonstrated (Byrne, Ervin, & Lamberth, 1970; Kleck & Rubenstein, 1975; Walster et al., 1966). However, there has been no consistent evidence about the importance of probability of acceptance. The primary purpose of this research is to determine what influence probability has on dating choice.

Previous attempts to evaluate probability of acceptance have generally compared the dating choices of attractive and unattractive subjects. Unattractive subjects are assumed to have a lower expectancy of being accepted by any given date. Therefore, these subjects would presumably choose less attractive dates than would more attractive subjects. This should be particularly true when the saliency of rejection is emphasized.

The results using this between-subjects approach have not been conclusive. Berscheid, Dion, Walster, and Walster (1971) found that unattractive subjects did choose slightly less attractive dates than did attractive subjects. However, they failed to find any differential effects when rejection was made more salient. In comparison, Huston (1973) found no difference in the dates chosen by attractive and unattractive subjects. However, he did find that all subjects chose more attractive dates when acceptance was assured. Other studies have generally led to equally inconclusive results.

This research was supported in part by Public Health Service Grants MH 22610 and MH 26002 from the National Institute of Mental Health. The authors wish to thank Sue Ellingboe for her assistance in running pilot subjects and in analyzing data from the studies reported here. We also wish to thank Norman Anderson, Michael Birnbaum, John Carroll, and John Payne for their helpful comments on various stages of the research.

In contrast to previous efforts, the present research was designed to study the influence of probability of acceptance for individual subjects. That is, rather than studying the effects of probability by a comparison between groups of subjects, analyses were made by using a within-subjects approach. The research strategy is thus based on analyzing the impact that probability has on the cognitive processes used by individuals in making dating choices.

A second but related purpose of this research was to investigate how probability is used in dating choice. That is, assuming probability is important, how is it combined with other information such as physical attractiveness? Several approaches suggest that attractiveness and probability should combine by multiplying. For instance, level of aspiration theory predicts that the desirability of a goal should be multiplied by the probability of attaining that goal (Lewin, Dembo, Festinger, & Sears, 1944). According to this view, dating choice should depend on the product of the desirability (or attractiveness) of the date and the probability of acceptance (Walster et al., 1966).

From a rather different viewpoint, subjective expected utility theory states that choices between risky alternatives (such as gambles) should depend on the product of the payoff times the probability of attaining the payoff (Edwards, 1961). Support for this multiplying rule of risky decision making has been found in several types of gambling situations (Shanteau, 1974, 1975). However, the rule has not been evaluated in more complex social judgment settings such as dating choice.

Formally, the multiplying rule can be written as

$$R = P \times PA, \qquad (1)$$

where the desirability of a date (R) equals the product of the probability of acceptance (P) and the physical attractiveness (PA) of the date. Statistically, Equation 1 predicts a significant interaction between probability and attractiveness that should be concentrated in the bilinear (Linear × Linear) trend component (Anderson & Shanteau, 1970; Shanteau, 1977).

Thus, the present studies were designed to determine whether probability is important in dating and, if so, to evaluate how probability is combined with attractiveness to arrive at a dating choice. In the first of three experiments, probability of acceptance was explicitly provided along with a photograph of the prospective date. This procedure allowed a direct assessment of the impact of probability and attractiveness on dating choice. In the second and third experiments, only photographs were provided, with the probability unspecified. Since probability was left up to each subject to infer, these studies were intended to mirror more closely actual dating situations.

Experiment 1

In Experiment 1, female subjects were asked to choose between two male dates. Each date was described by a photograph and a verbal statement of the probability that he would agree to go out with the subject. Both the attractiveness of the photographs and the probability of acceptance were systematically varied in a factorial design. This design permitted a straightforward analysis of whether probability influenced the subjects' judgments. It also allowed a direct assessment of how probability is combined with physical attractiveness in making a dating choice.

Method

Subjects. Fifteen female undergraduates were each paid $1.50 per hour to participate in the research. The females were all unmarried, free to date, and between 17 and 22 years old. All subjects were run individually.

Stimuli. Subjects made preferential choices between two dates such as "Tom/Fairly likely" and "Joe/Unlikely." The names referred to photographs on a nearby display board; the verbal probability phrase represented the likelihood that the pictured male would be willing to go out with the subject on a date.

The stimulus information was presented on index cards with one date on the left side of the card and the other on the right. There were 140 data pairs from a 7 (left probability) × 5 (left photo) × 2 (right probability) × 2 (right photo) factorial design. For the left date, the seven probability phrases were Sure thing, Highly likely, Fairly likely,

Toss-up, Somewhat unlikely, Very unlikely, and No chance. These were combined with five photographs that varied from quite attractive to unattractive. For the right date, the probabilities were either Likely or Unlikely, and either an attractive or an unattractive photograph was used. The left and right dates were counterbalanced so that each photograph and probability appeared equally often on each side of the card.

The photographs were candid yearbook shots and were selected on the basis of preliminary ratings to cover a wide range of physical attractiveness. The names identifying the photographs were the seven most common male names (John, Bob, Bill, Jim, Tom, Joe, and Dick) listed by Battig and Montague (1969, p. 35); the names were randomly assigned to the photographs. The verbal probability phrases were selected on the basis of normative ratings (Lichtenstein & Newman, 1967) to cover a wide range; these same phrases have also been used in prior research (Shanteau, 1974, 1975).

Procedure. The subject's task was to compare the two dates on a stimulus card and to "make a choice as to which you would prefer." Although the subject was aware that she would not actually go out on a date, an attempt was made to make the task meaningful. For instance, photographs were taken of all subjects comparable to the pictures of male dates. The subjects were to assume that the probability phrase represented the male's reaction after seeing her photograph.

The subject indicated her date preference by locating a pointer on a 40-cm unmarked response bar. The left end of the bar was defined as a "very strong preference for the date on the left," and the right end was defined as a "very strong preference for the date on the right." The middle of the scale represented "no preference between the two dates." The ends of the response bar were also exemplified by anchor stimuli that were more extreme than any of the experimental stimuli. These anchors were used to decrease the possibility of floor or ceiling effects.

After presenting each dating pair, the experimenter recorded the subject's response to the nearest millimeter, using a ruler on the rear of the scale. The scale ranged from +100 on the left to −100 on the right.

The experiment consisted of three daily 1-hour sessions. The initial part of the first session was devoted to instructions and practice. Following the practice, the subject was required to correctly summarize the instructions back to the experimenter. The entire set of experimental stimuli was then presented. Sessions 2 and 3 began with a brief summary of the instructions. In Session 2, the complete set of stimuli was presented for a second time; two more replications were then administered in Session 3. Prior to each replication, the stimulus cards were shuffled to provide a different random presentation order.

Results

The group mean preference responses for the left dates averaged over the right dates are plotted in Figure 1. For example, the top right point corresponds to the mean preference for the photograph of Tom when it was paired with a Sure thing probability; the mean response in this case was roughly +65.

The names have been spaced along the horizontal axis according to their marginal means and reflect the attractiveness of the corresponding photos: the farther to the right, the more attractive the photograph. Thus, Tom and Bob were seen as highly attractive, John and Jim were of intermediate attractiveness, and Bill viewed as fairly unattractive.

Each curve in Figure 1 corresponds to the listed probability. As can be seen, preference for dates increases as the probability becomes more certain. For instance, "Tom/Sure thing" has a much higher preference than "Tom/No chance."

The results in Figure 1 not only suggest that probability of acceptance is important but also bear on the combination rule used to integrate probability with attractiveness. The multiplying model in Equation 1 predicts that the seven curves in Figure 1 should form a fan of straight diverging lines (Anderson & Shanteau, 1970). As can be seen, the lines are very nearly linear and diverge in the predicted fashion. Similar-appearing results were obtained for all 15 females when individual-subject data were plotted.

Statistical analyses. The results for each subject were analyzed by separate analyses of variance. For all subjects, the probability and photograph main effects were both highly significant. In addition, all 15 subjects revealed a significant Photograph × Probability interaction as shown in the second column of Table 1. While these results are expected from Equation 1, the model makes precise predictions about the form of the interaction. In particular, the Photograph × Probability interaction should be concentrated in the bilinear trend component. This means that after the bilinear term is removed, the residual component should be nonsignificant. Using the procedure described in Shanteau

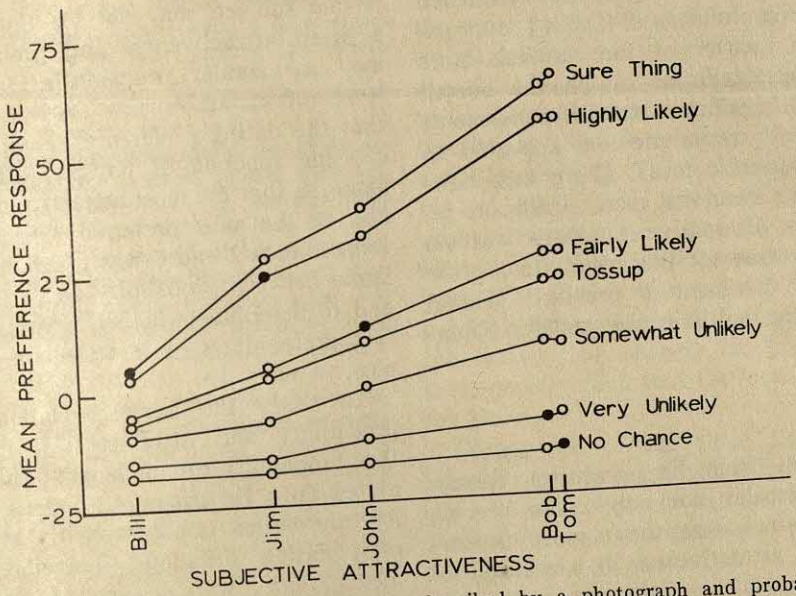

Figure 1. Mean preference responses for dates described by a photograph and probability of acceptance, Experiment 1. (Each point is averaged over four alternative dates. Photographs are spaced along the horizontal axis according to their marginal means; probabilities are listed as curve parameters. Filled points are discussed in the text.)

(1977), 11 of the 15 subjects were found to have nonsignificant residual components, as listed in the third column of Table 1. While the remaining 4 subjects showed significant residuals, the Fs are quite small, and plots of individual data revealed no systematic pattern of deviations from bilinearity.

Similar analyses were also performed sepa-

rately for each choice alternative. As listed in the last four columns of Table 1, approximately one quarter of the residuals were found to be significant. As in the overall analysis, the significant residual components were of small magnitude and appeared to have no systematic locus. There was, however, a slight trend for more significant residuals with Alternative 4; there was no identifiable reason for this result. In all, the results of Experiment 1 provided general support for the multiplicative model in Equation 1.

Discussion

The results from Experiment 1 clearly show that females not only make use of probability information, they appear to combine it with attractiveness in a multiplicative fashion. Thus, a date who is low on either factor (i.e., very unattractive or very unlikely to accept a date) will be seen as undesirable.

It is commonly believed that there is an inverse relation between attractiveness and probability (e.g., Walster et al., 1966). This means that highly attractive dates should have a low probability of acceptance, and unattractive dates should have a high probability. If the multiplying rule holds, then this inverse relation between attractiveness and probability implies that dates of intermediate physical attractiveness (and intermediate probability of acceptance) will be most preferred.

This effect is graphically illustrated in Figure 1. Five points have been filled based on an assumed negative relation between attractiveness and probability. For example, the least attractive date (Bill) was given the highest probability (Sure thing), whereas the most attractive date (Tom) was given the lowest probability (No chance). As can be seen, the filled points peak for dates of intermediate attractiveness. In this example, moderately attractive Jim with a Highly likely probability would be the most desirable.

Of course, this prediction depends on the presence of a negative relation between attractiveness and probability. One alternative is that subjects may not see any connection between attractiveness and probability (or may see similar probabilities for different levels of attractiveness). This would imply that the dating preferences would be an increasing function of physical attractiveness alone, so that the most attractive dates would also be the most preferred. One purpose of Experiments 2 and 3 was to examine the relation between probability and attractiveness and to determine whether subjects would in fact prefer dates of intermediate attractiveness.

To study the natural relation between probability and attractiveness, it is clear that probability cannot be artificially manipulated as in Experiment 1. Indeed, probability information is not explicitly available in most dating situations. Therefore, Experiments 2 and 3 were designed so that subjects would have to infer or evaluate probability based on other information (i.e., a photograph).

Experiments 2 and 3

In Experiments 2 and 3, subjects made preferential choices between pairs of dates described by photographs alone. This allowed a direct assessment of whether factors other than physical attractiveness influence dating choice. One additional purpose of Experiments 2 and 3 was to evaluate the multiplying rule for attractiveness and probability in a setting where probability was not explicitly provided.

Experiment 2 was run as a continuation of Experiment 1 using the same subjects. However, it is possible that the explicit presentation of probabilities in the first experiment may have alerted these subjects to the use of probability in the second experiment. Therefore, Experiment 3 was run on a new group of female subjects who had not gone through Experiment 1 initially.

Method

Subjects. In Experiment 2, the 15 females used in Experiment 1 returned for one additional session. In Experiment 3, 14 new subjects with similar characteristics were run under the same conditions.

Procedure. Subjects were initially presented with the seven photographs of males used in Experiment 1 and were asked to carefully consider the dating potential of each of the males. It was then explained that several facets of dating desirability would be examined in the experiment.

Subjects began by estimating the probability that each of the males would accept a date with her after viewing her photograph. In making these estimates, subjects were instructed to keep in mind that the male would be assured of her willingness to accept a date; this was done because several pilot subjects indicated that unattractive males might not choose them because the males would fear rejection.

Subjects responded by locating a pointer along a 40-cm unmarked bar. The left end of the bar was defined as "No chance" and the right end was defined as "Sure thing." The experimenter read the responses from the rear face of the scale using a 0–100 scale. The stimuli were presented four times in all, with a different random order each time.

Subjects were then asked to rate the physical attractiveness of each of the pictured males. The subject's task was to "disregard any other feelings you may have about the picture while making this rating—tell me only how physically attractive you consider this person to be." This instruction was provided because some pilot subjects stated that they were taking into account the possibility of reciprocal interest by the males. The basic experimental procedure was the same as for the probability ratings, except that the ends of the scale were defined as "Extremely unattractive" and "Extremely attractive."

Finally, subjects made preferential choices between pairs of dates in which each date was described by just a photograph. As in Experiment 1, subjects were aware that they would not actually go on a date. However, subjects were instructed to assume that they were in an actual dating situation and to make choices taking into account all factors that might be important in choosing a date. Furthermore, it was emphasized that in this dating situation, like any other, it would be unclear whether their dating choice would reciprocate.

Twenty-one pairs of dates were formed from all possible combinations of the seven photographs. For each pair, subjects responded by first giving the name of the chosen date. They then indicated the degree of their preference by using the same response scale as in Experiment 1. The scale was defined as before, except that anchor stimuli were not used to define the ends of the scale. The 21 choice pairs were presented four times, with a different shuffled order each time. Finally, each subject was debriefed and interviewed regarding her thoughts on dating and her approach to making dating choices.

Results of Experiment 2

Results for three representative subjects are graphically presented in Figure 2. The spacing along the horizontal axis for each of the three panels reflects the subject's physical attractiveness ratings of the photographs. Subject (S)1, for example, considered Dick to be the most attractive, Joe to be least attractive, and Bob to be of roughly intermediate attractiveness. The starred points at the top of each panel represent the subject's probability estimates (e.g., S1 assigned the lowest probability to Jim and the highest to Joe). The filled points indicate the subject's mean preference for each date relative to all others (e.g., S1 showed the greatest mean preference for Tom and the lowest preference for Joe).

Comparison of the three panels reveals several types of individual differences. In the physical attractiveness ratings, for instance, Bob was given the highest rating by S5 and S13, whereas S1 rated Bob as only moderately attractive. There were also considerable differences in subjects' probability ratings, with S1 and S5 giving low probability estimates to highly attractive dates, whereas S13 rated all dates fairly high on probability. Perhaps the most pronounced differences were in the preference values; although Dick was highly preferred by S13, he was one of the least preferred by S1 and S5. Individual differences of comparable magnitude were observed for the remaining subjects as well.

In spite of these differences, subjects revealed some important similarities in the shapes of their preference curves. The left and center panels of Figure 2 are representative of results obtained for 11 of the 15 subjects; the plots show a peaked preference curve with the greatest preference for dates of intermediate attractiveness. Further, there is a marked similarity between the probability and the preference curves. Thus, these 11 subjects preferred dates of intermediate attractiveness, and it appeared that probability was related to these intermediate preferences.

As exemplified by S13, the remaining four subjects revealed a rather different preference pattern. These subjects showed an increasing curve and preferred the most attractive dates; moreover, their probability estimates were generally flat, with little relation to the

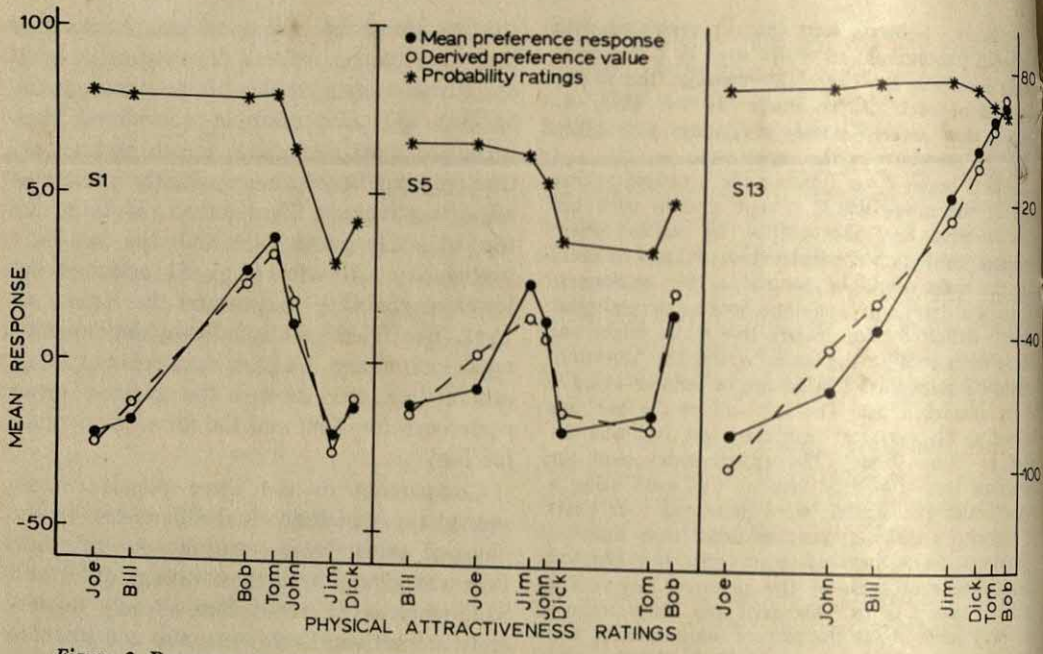

Figure 2. Responses to dates described only by photographs for three typical subjects (S), Experiment 2. (Horizontal spacing reflects physical attractiveness ratings for each date. Stars give probability-of-acceptance ratings for each date. Filled points show mean preferences for each date compared to all others. Open points give values derived from a multiple regression model.)

preference curve. Therefore, these four subjects appeared to be basing their preferences primarily on the attractiveness of the dates.

Statistical analyses. In order to quantitatively describe each individual's responses, separate multiple regression analyses were performed. The basic strategy was to derive a regression equation to predict each subject's preference values based on (a) her probability ratings for each date, (b) her physical attractiveness ratings for each date, and (c) the cross-product values derived by multiplying probability and attractiveness ratings together. Thus, the multiple regression model was based on

$$J = \beta_1 (\text{Physical Attractiveness}) + \beta_2 (\text{Probability}) + \beta_3 (\text{Physical Attractiveness} \times \text{Probability}). \quad (2)$$

The subject's mean preference judgment (J) is expressed as a function of the attractiveness and probability ratings; the weighting constants (β) represent standardized weights derived from a multiple regression analysis.

The prediction terms that accounted for a significant proportion of variance in the preferences of each subject are listed in the second column of Table 2.[1] The terms are listed in their order of variance accounted for. The subjects were placed into two groups depending on whether they preferred dates of intermediate attractiveness (peaked curve) or dates of greatest attractiveness (increasing curve).

As expected, the physical attractiveness

[1] When predictor terms are intercorrelated, as is the case here, the squared semipartial correlation is the best indicant of a term's significance (Darlington, 1969). The squared semipartial correlation measures the contribution of a predictor term after the variance accounted for by all preceding terms has been removed. Thus, when predictors are intercorrelated, the semipartial correlation depends heavily on the order in which terms are entered into the regression analysis. To alleviate this problem, the order should be determined on the basis of theory or some other predetermined criterion (Kerlinger & Pedhazur, 1973). In this experiment, the shapes of the preference curves were predictive of certain combination rules (e.g., a multiplicative rule for subjects with a peaked preference curve) and were therefore used to determine the order in which terms were entered into the regression analysis.

term accounted for the most variance for three of the four subjects who chose the most attractive dates. Of more interest, the cross product was dominant for 9 of the 11 subjects who preferred dates of intermediate attractiveness; for these subjects, probability did appear to influence dating preferences in the form of a multiplicative combination of attractiveness and probability.

Of additional interest, several of the subjects who chose dates of intermediate attractiveness also revealed a significant attractiveness term (e.g., S5). These subjects generally had preference curves in which the greatest preference was for a date of intermediate physical attractiveness, but there was also a moderately high preference for the most attractive date (as seen for S5 in Figure 2). This may represent a compromise strategy between a simple peaked strategy (e.g., S1) and an increasing preference strategy (e.g., S13).

To determine whether each subject's regression equation could adequately describe her preference judgments, the discrepancies between actual and derived preferences were examined. As illustrated by the open circles in Figure 2, the discrepancies were visually quite small. This result suggests that the predictor terms listed in Table 2 for each subject provided a reasonable account of the preferences.

At a statistical level, however, analyses of the discrepancies revealed small but consistent significant differences. When tested against within-cell error, significant discrepancies were observed for 10 of the 15 subjects, including S5 and S13 in Figure 2. Examination of these discrepancies generally revealed that they were quite small. Therefore, it appears that the regression equations provide at least a reasonable first approximation to the preferences.

To further examine the usefulness of the

Table 2
Significant Predictor Terms and Number of Correctly Predicted Choices From Regression Equations and Attractiveness Ratings for Subjects Showing Peaked and Increasing Preference Curves

Note. PA = physical attractiveness; Prob. = probability.

derived regression equations, three post hoc analyses were conducted. The first was based on the ability of each subject's equation to account for her dating choices. The number of choices that could be correctly predicted is presented in the third column of Table 2. Out of a total of 21 choices, an average of 19.0 choices were accounted for by the regression equation (which are based on attractiveness and probability ratings). This ranged from a low of 15 to a high of all 21 correct. More detailed inspection revealed few errors of any magnitude, and most errors occurred when there was little or no difference in the preference ratings. Thus, the choices of most subjects could be accounted for quite well by the predictions obtained from the regression equations.

The second post hoc analysis involved a comparison between choice predictions based on the regression equations and choice predictions based on physical attractiveness values alone. This analysis bears directly on the issue of whether probability is an important component in subjects' preferences. The number of choices that could be correctly predicted based on attractiveness ratings is shown in the right column of Table 2. Out of a total of 21 choices, attractiveness alone was able to account for an average of 17.0 correct choices, with a low of 11 and a high of 21 correct. Many of the errors, however, were quite large. As expected, attractiveness alone was able to account for the choices of the four subjects whose preference curves increased with attractiveness (e.g., S13). In comparison, attractiveness alone was inferior to the regression equation for most of the 11 subjects who preferred dates of intermediate attractiveness (e.g., S1 and S5).

The final post hoc analysis was designed to examine the credibility of the direct ratings of attractiveness. The regression model in Equation 2 depends crucially on these ratings, and any bias or distortion in the ratings can greatly influence the form of the regression equation (Schmidt, 1973). However, substitution of attractiveness values derived for each subject in Experiment 1 into Equation 2 produced no substantial differences in the resulting regression equations. Thus, the present direct rating procedure apparently produced reasonable estimates of individual subjective values.[2]

Results of Experiment 3

The results obtained from the new set of subjects substantially replicated the findings of Experiment 2. For instance, analysis of the preference curves revealed that 9 of the 14 subjects preferred dates of intermediate attractiveness, whereas five subjects preferred the most attractive dates. Comparison of actual preferences with the preferences derived from the regression equation produced only small visual differences; however, the discrepancies were significant for 11 of the 14 subjects. Finally, 18.1 of the 21 choices could be correctly predicted from the regression equations. In all, the results from Experiment 3 were quite similar to those of Experiment 2. This suggests that the results are not dependent on the subjects having prior experience in Experiment 1.

General Discussion

There were two questions addressed in this research: (a) Is probability of acceptance important in choosing a date? (b) How is probability combined with physical attractiveness in making a choice? The discussion will consider the implications of the present findings for these two questions.

Is Probability Important?

The answer from all three of the present experiments is clear and unequivocal: Yes, probability is important in choosing a date.

---

[2] This analysis also bears on an important issue involving scale constants. The addition of constants to any of the terms in Equation 2 can potentially change the form of the derived regression equation. Moreover, since only the direct ratings of probability can be assumed to be on a ratio scale (because probability has a meaningful zero value), the interval scale of attractiveness values may be particularly suspect. The fit of the multiplying model in Experiment 1, however, provides attractiveness estimates on a ratio scale (Shanteau, 1974). Since the substitution of these values into the regression analysis did not change the basic results, the derived regression equations are apparently not subject to problems of scale constants.

Probability was used by subjects when it was explicitly provided in Experiment 1 and when it was left for subjects to infer in Experiments 2 and 3. There is little doubt, therefore, that the females in this research used probability of acceptance in making their dating choices.

The present findings on the importance of probability contrast with previous research that reports little or no effect of probability (e.g., Berscheid et al., 1971; Huston, 1973). There are, however, several design and procedure differences that may account for the discrepancy in results.

To begin with, the present research was designed to isolate the effects of probability without concern for the subject's own level of physical attractiveness. In contrast, prior studies have generally studied probability by comparing the dating choices of attractive and unattractive subjects. However, if there is a small or a diffuse relation between subjects' attractiveness and their use of probability, then this research approach may not be sensitive to the effects of probability.

An attempt was made in the present study to determine whether there was any connection between a subject's attractiveness and her use of probability.[3] However, no evidence was found of any relationship between a subject's appearance and her probability inferences. A further argument against comparing groups comes from the widespread individual differences in Experiments 2 and 3. These differences suggest that subjects' perceptions of probability and attractiveness may vary quite widely. Therefore, analyses based on comparing group differences between attractive and unattractive subjects may well be incapable of detecting the presence of probability effects.

Another difference from past research was that the present subjects did not actually expect to go out with their dating choice. Previous studies, in contrast, have generally attempted to simulate actual dating situations in various ways (Huston & Levinger, 1978). It may be, then, that the present subjects were isolated from "real world" demands, and they might have used probability in the laboratory when in fact they would not normally use such information.

Several lines of evidence, however, suggest that the subjects in this research did approach the present tasks in a manner analogous to choosing real dates: (a) Subjects' verbal reports indicated that they were thinking about the present tasks in much the same way as they would think about real dates; (b) many subjects became quite personally involved in the research, even to the point of wanting to know how they could find out more about the pictured males; and (c) the widespread individual differences between subjects suggest that each subject was carefully evaluating the dates by her own standards and not simply following some stereotypic set of peer standards. Therefore, it would appear that probability was an important factor for the present subjects in their general approach to dating.

How Is Probability Used?

The answer is that, at least to a first approximation, probability is combined with physical attractiveness by multiplying. The visual evidence in support of multiplying, especially in Figure 1, seems quite compelling. However, the presence of small but consistent statistical discrepancies in Experiments 2 and 3 means that the model may not be entirely adequate.

One possible explanation for these discrepancies from multiplying is that subjects may use other information besides probability and

---

[3] If the subject's own physical attractiveness is related to her expectancy of acceptance, then the subject's attractiveness should be related to the dating strategy employed. For example, subjects who always chose the most attractive dates might be expected to be more attractive than subjects who chose dates of intermediate physical attractiveness. Contrary to this prediction, no such relation was observed. Ratings of the subjects' photographs by 60 male undergraduates revealed little or no relationship between the physical attractiveness of a subject and the dating strategy she employed. For example, S1 and S13 in Figure 2 were nearly equal in rated attractiveness, but employed very different dating strategies. It appears, therefore, that the subject's attractiveness does not determine her expectancy for acceptance. Of course, the possibility remains that self-perceived attractiveness (as opposed to outward attractiveness) may be related to probability.

attractiveness in making their choices. One conjecture, by Shanteau and Nagy (1976), is that females may also rely on their inferred compatibility with prospective dates. Evidence for this possibility came from comments by the subjects to the effect that "he is (or is not) my type," and so "we would (or would not) get along together." Therefore, the present discrepancies from multiplying may indicate that more than attractiveness and probability information was being combined when subjects were making choices.

The use of factors other than probability and attractiveness might explain why the multiplying model fit well in Experiment 1 but less well in Experiments 2 and 3. In the first experiment, probability and attractiveness were explicitly manipulated, and the data supported multiplying; there was little opportunity in this experiment for other variables to have any effect. In Experiments 2 and 3, however, only physical attractiveness was manipulated, and subjects were encouraged to use any other information they might actually rely on in choosing dates. Thus, there was an opportunity for compatibility (or other factors) to influence the choices; this would then decrease the fit of the multiplying model, which is based only on attractiveness and probability.

Nevertheless, the model still did impressively well in accounting for subjects' dating choices in Experiments 2 and 3. The derived model accounted for over 90% of the subjects' choices; in comparison, a model based on physical attractiveness alone was able to account for only 75% of the choices for subjects who preferred dates of intermediate physical attractiveness. Thus, combining probability and attractiveness information does an appreciably better job than attractiveness alone. Including information on compatibility or other factors may, of course, increase the percentage even more.

Finally, it is appropriate to make some comment on the general research strategy used in this study. The progression from controlled to more naturalistic research in a single study has been praised by some (Byrne et al., 1970) and criticized by others (Ebbessen & Konečni, 1975). In the present research, this strategy proved quite useful in, among other things, evaluating the strengths and weaknesses of the multiplying rule. The results from the three experiments suggest that probability and attractiveness probably do combine by multiplying, but in more naturalistic settings other factors may enter in as well.

The progression of studies was also useful in empirically deriving the prediction from Experiment 1 that subjects might prefer dates of intermediate attractiveness. This prediction was borne out in Experiments 2 and 3 for roughly two thirds of the subjects. Even the deviations from this pattern were interesting, since they indicate that a substantial minority of females may rely primarily on physical attractiveness in choosing dates.

In all, the present research illustrates how a combination of controlled and more naturalistic research may be more beneficial than either approach taken alone. Together with other studies using a similar strategy (e.g., Phelps & Shanteau, 1978), this study suggests that combining controlled and naturalistic research may prove quite useful in future research involving complex human judgment.

Consequences of Responsiveness in Dyadic Interaction: Effects of Probability of Response and Proportion of Content-Related Responses on Interpersonal Attraction

Deborah Davis
University of Nevada, Reno

William T. Perkowitz
Loyola University

"Responsiveness" is defined in terms of two sequential response contingencies: (a) the probability with which each person in an interaction responds to the communicative behaviors of the other, and (b) the proportion of responses that are related in content to the preceding behaviors of the other. Two experiments examined the effects of responsiveness in a verbal exchange on attraction. Under the guise of a study of the "acquaintanceship process," 176 male and female subjects exchanged information about themselves with another subject (actually a same-sex confederate) by taking turns choosing and answering one of either two or three questions about themselves on each trial. For Experiment 1, subjects were required to answer on all trials, whereas the probability and frequency with which the confederate responded to the subject were orthogonally manipulated. For Experiment 2, the proportion of content-related responses was varied. The confederate answered the same question as the subject on either 80% or 20% of the trials. Both the probability of response and the proportion of content-related responses were positively related to (a) attraction to the confederate, (b) subjects' perceptions of the confederate's attraction to themselves, and (c) the degree to which subjects felt that they and the confederate had become acquainted with one another.

Social interaction has been described as "the very stuff of human life" (Goldschmidt, 1972, p. 59). Certainly, at the least, it may be described as the "very stuff" of human relationships. Relationships are formed and maintained through a series of interactions and are often formed simply for the sake of interaction.

Despite the importance of interaction, by far the majority of empirical research on love, attraction, and friendship has focused on the effects of static characteristics of others (e.g., similarity, physical appearance, personality or behavior descriptions, etc.). Although such characteristics are undeniably important, adequate analysis of the determinants of attraction must also relate the process of interaction to attraction. The present article is concerned with one dimension of interaction—responsiveness—which, it is argued, functions as a major determinant of the quality of interaction and, hence, attraction.

Because the present concept of responsiveness is new to social psychology, before describing two empirical studies relating responsiveness to attraction we will (a) define responsiveness and distinguish it from other related concepts, (b) describe the functions of responsiveness and their implications for attraction, and (c) summarize relevant literature.

The Concept of Responsiveness

Responsiveness is defined in terms of two sequential contingencies: (a) the probability with which each participant responds (either

We are indebted to David Biscardi and Rita Hargood, who served as confederates, to Mark McDade, who built the apparatus for Experiment 1, and to Roger Bakeman, Timothy C. Brock, Thomas M. Ostrom, and Robert S. Wyer, Jr., for their comments on previous drafts of this manuscript.

verbally or nonverbally) to the communicative behaviors of the other and (b) the proportion of responses that are related in content to the preceding communicative behavior of the other. It should be noted that the first contingency (probability of response) is applicable to both related and unrelated responses. It is assumed that an unrelated response is better than no response. With regard to the second contingency (relatedness of response content), three conceptual distinctions should be emphasized.

Perception of relatedness versus logic or intent of the speaker. We would like to stress that what is important for attraction is the *perception* that the other's responses are related to one's own communications. Responsiveness is "in the ear of the beholder," so to speak. If a response is perceived to be unrelated, it will be functionally eqivalent to any other unrelated response, regardless of whether it was logically related, or intended by the speaker to address the preceding communication.

Content versus causality. The relationship between the *content* of successive responses should not be confused with the nature of the *causal* relationship between them. Jones and Gerard (1967), for example, classify interactions into four categories that vary in the extent to which each participant's behaviors are *determined* by the preceding behavior of the other versus by his or her own "plan" for the interaction. Likewise, Mehrabian's (1969, 1970, 1971) definition of responsiveness focuses on the extent to which one's behaviors are influenced by those of the other. For Mehrabian, responsiveness is indexed by the amount of *change* in one's behaviors (e.g., facial and vocal expressions, rate and volume of speech, etc.) resulting from another's presence or behavior.

In contrast, the present concept of relatedness of response content is concerned only with the degree to which the response is perceived to address itself to the content of the preceding message. Responses that are determined or influenced by the other's preceding behavior may nevertheless be unrelated in content—as in the case of unrelated associations that may be triggered by the other's behavior. These responses will, however, be more frequently characterized by related content than those not influenced by the preceding behavior. On the other hand, responses that are not causally related may be related in content. In this case, the frequency with which related responses will occur will depend upon the frequency with which responses that are related in content arise independently.

Relatedness versus valence. A related response need not be positive. It may be friendly, hostile, agreeing, disagreeing, defiant, cooperative, and so on. A punch in the nose and a pat on the back may be equally related to a preceding behavior, although different in valence. We are concerned here only with the degree to which each behavior addresses the content of the preceding behavior, not with the way in which it does so. This is not to say that valence has no effect on attraction, but rather that valence and relatedness are independent in their effects.

The Functions of Responsiveness—Why is it Important?

When two persons interact, each expects the other to be responsive—to respond to his or her communicative behaviors, and to respond with content that addresses itself to the intended message. As Ruesch and Bateson (1951) have pointed out, each behavior in an interaction has a certain "demand" aspect, requiring a response of a certain kind. Certainly, in order to fulfill the demand, the response must address the content of the preceding behavior. We expect a question to be followed by an answer, or an expression of disgust with the weather by a comment on the same. Changes of subject are, of course, acceptable, but only after at least a brief related response. Such mutual responsiveness between the participants will serve at least four functions for the interaction, each with potential implications for attraction.

Maintenance of interaction. Perhaps most fundamental of the functions of responsiveness is its role in the maintenance of interaction. Although interactions may persist in the face of occasional failure to respond (as indeed occurs in virtually all interactions), repeated failure to respond will typically result in cessation of interaction. Likewise,

irrelevant responses do not facilitate interaction and, in fact, are frequently used to either terminate an interaction or to change the subject (Watzlawick, Beavin, & Jackson, 1967). Attraction has been shown to be a positive function of the opportunity for interaction (e.g., Ebbesen, Kjos, & Konečni, 1976; Festinger, Schachter, & Back, 1950) and of the frequency of interaction (Brockner & Swap, 1976; Byrne, 1961; Kipness, 1957; Saegert, Swap, & Zajonc, 1973). Through its influence on the maintenance of interaction, responsiveness should likewise facilitate attraction.

Predictability, control, and stress. To the extent that another is responsive, his or her behavior will be in some degree predictable. Although the exact content of a response is typically not predictable, one may at least expect (a) that the other *will* respond and (b) that the response will address the content of the preceding message. If the other is unresponsive, even this degree of predictability is lost.

Similarly, the degree to which the other is responsive will affect the magnitude of control one may exert over the course of the interaction. Clearly, one cannot often exert complete control. Neither the exact content of the other's responses nor the specific nature of the behaviors the other will initiate will typically be controllable. However, responsiveness from the other will allow some degree of control, in that one can (a) cause the other to respond and (b) determine the general topic area (albeit not the specific content) of the response.

Because of the constant uncertainty associated with unpredictability and the frustration associated with lack of control, interaction with an unresponsive other will be stressful. Arnold, Veitch, and Arkkelin (Note 1), for example, have recently demonstrated that social situations that are perceived as most uncomfortable are those characterized by both high arousal and lack of control. Since others who are associated with stress should be less attractive than those who are not, again, it follows that responsiveness will influence attraction.

Facilitation of interaction goals. To the extent that responsiveness facilitates control over the course of the interaction, it should also facilitate interaction goals. Most behaviors or communicative acts in interaction have a purpose. It may be as simple as the maintenance of interaction or as complex as an attempt to manipulate or persuade. Whatever the goal of the act, response from the other is necessary, but not sufficient, for its fulfillment. Although response may or may not facilitate the initiator's purpose, failure to respond will almost certainly frustrate it. Similarly, related responses will be more likely to facilitate interaction goals than will irrelevant responses. Since others who are associated with reward (facilitation of interaction goals) should be more attractive than those associated with punishment (frustration), responsiveness would again be expected to facilitate attraction.

Communication of interpersonal affect. The degree of responsiveness between participants in an interaction reflects the relationship between them—their interest in one another, as well as in their respective communications. When interacting with another who frequently either fails to respond or responds irrelevantly, one is tempted to conclude that the other is interested neither in oneself nor in what one has to say. Certainly, one is left with the feeling that no real "interaction" has taken place, and that no "relationship" has been developed. Responsive interaction, on the other hand, will facilitate the perception of a "relationship" between the participants as well as the perception of mutual interest and attraction.

As Heider (1958) has argued, the perception of a "unit" relationship should produce a corresponding sentiment relationship (attraction). Similarly, attraction to another is facilitated by the perception that he or she is attracted to oneself (e.g., Backman & Secord, 1959; Harvey, Kelley, & Shapiro, 1957; Jones, Gergen, & Davis, 1962). Responsiveness, to the extent that it strengthens the perception of a bond between the participants and of mutual interest and attraction, should likewise facilitate attraction.

Empirical Evidence

Although research on attraction has not dealt explicitly with responsiveness, evidence

of its importance has appeared in several lines of research. Responsiveness is defined in terms of two response contingencies—probability of response and relatedness of response content. The existing literature relevant to the two response contingencies is summarized below.

Probability of response. Response to another's behavior may be as simple as an orienting response or other indication of attention or as complex as an elaborate compliment. The power of attention as a reinforcer has been well documented by the countless reports of the use of "differential attention" as a technique for behavior modification (see Hersen & Barlow, 1976, pp. 339–352). Verbal and nonverbal responses indicating attention to another have also been shown to facilitate attraction. Research on eye contact (cf. Ellsworth & Ludwig, 1972), for example, has demonstrated that under appropriate circumstances, visual attention to another will facilitate attraction. Likewise, Rosenfeld's (1966) work on affiliation has documented the importance of verbal indicators of attention or acknowledgment. Rosenfeld recorded various verbal and nonverbal behaviors of subjects instructed to either seek or avoid approval from a naive interlocutor (interlocutress). Approval seekers used more "recognitions" (e.g., brief utterances such as "Mmhmm," "Hmmm," "Yeah," "No kidding?" "Really?", etc.) than approval avoiders; and furthermore, "recognition" scores were positively correlated with approval actually received from subjects' naive partners. Finally, research on physical pleasuring (Davis & Brock, in press; Davis & Martin, 1978; Davis, Rainey, & Brock, 1976) has shown that attraction to a recipient of physical pleasure is facilitated by responsiveness. Recipients who responded to receiving pleasure (by expressing enjoyment) were liked better than those who remained silent.

The importance of response has been further documented by studies of mother–infant interaction. Maternal responsiveness has been shown to facilitate both attachment to the mother and the development of behavioral competence for the infant (see Appleton, Clifton, & Goldberg, 1975, and Martin, 1975, for reviews of this literature). Konner (1975) has also stressed the importance of responsiveness, pointing out that children often prefer to interact with older children or adults, rather than peers, because the former are more "contingently responsive"—presumably with respect to both probability and relatedness of response.

Finally, in a series of studies of responsiveness and social attraction between rodents, Latané and his colleagues have demonstrated that while static qualities of the animals (e.g., color, texture, smell, etc.) do not affect attraction, attraction is strongly influenced by factors affecting the capacity for movement and response (see reviews by Latané & Hothersall, 1972; Werner & Latané, 1974). Rats are relatively unattracted, for example, to caged, stuffed, or anesthetized rats, whose capacity for response is restricted, and to unresponsive objects (e.g., tennis balls, warm water bottles, Plexiglas tubes, etc.), but are quite attracted to a responsive human hand. Additionally, attraction is facilitated when the capacity for response is enhanced by injection of adrenaline or caffeine, and it is inhibited when rats are made sluggish by injection of chlorpromazine or alcohol.

While the results of the research described above are consistent with the hypothesis that attraction will vary positively with the probability of response, the various manipulations (e.g., anesthetizing, stuffing, eye contact) and measures (e.g., recognitions) have involved initiative as well as responsive behaviors, and have not varied the probability of response independently of response valence, and in relation to specified units of perceiver behavior.

Relatedness of response content. Although the concept of relatedness of response content has not been prominent in social psychological theories of love and attraction, it has played an important role in other areas of research.

The problem of unresponsive interaction, under the label "disqualification," has been prominent in discussions of mental illness and family and marital dysfunction. "Disqualifications" are responses that "invalidate" the messages that evoke them (Danziger, 1976). Such invalidation may be achieved by changing the subject, failure to respond, ignoring the message, misunderstanding, interruption,

tangentialization, literal interpretation of metaphors and vice versa, and so forth—essentially, by irrelevant or unrelated responses. The concept of disqualification has been central to the double-bind theory of schizophrenia (e.g., Bateson, Jackson, Haley, & Weakland, 1956; Sluzki, Beavin, Tarnopolsky, & Vernon, 1967), and interactions marked by frequent disqualifications have been indicted as contributors to inadequate development of the self-concept (e.g., Laing, 1961) and have been shown to characterize dysfunctional marriages and families (e.g., Watzlawick et al., 1967; Williams, 1969; Follingstad & Haynes, Note 2).

Deriving from the client-centered tradition, responsiveness has played an important role in counseling and psychotherapeutic theory and technique—under the label "empathy." "Empathic understanding," for example, as defined by Carkhuff and Berenson (1967), is defined in terms of the extent to which the content of the therapist's responses reflects understanding of, and addresses itself to, the true meaning (both verbal and emotional) of the client's communications. The ability of the therapist to facilitate the client's problem solving and growth, they argue, is directly related to the depth of the counselor's empathic understanding.

Finally, in contrast to the intimacy of therapist–client or family and marital relationships, Petty and Brock (1976) have studied the effects of relevant versus irrelevant responses from a public speaker to a heckler. The degree to which the speaker's responses were related in content to the heckler's comments significantly affected the audience's agreement with, and reactions to, the speaker. Relevant responses produced significantly greater agreement with the message than irrelevant responses, and the responsive speaker was perceived as more competent than the unresponsive one.

Again, although the literature summarized above is suggestive of the relationship between responsiveness and attraction, direct empirical evidence is lacking. The present two experiments were designed to test the hypothesis that attraction will vary positively with responsiveness. Experiment 1 dealt with the first component (probability of response) and Experiment 2 with the second component (relatedness of response content). As argued earlier, responsiveness will serve to communicate interest and attraction, as well as to strengthen the perception of a "relationship" between participants. Thus, it was also expected that responsiveness would affect subjects' perception of the other's attraction toward them and the degree to which they felt that they and the other had become acquainted with one another.

Experiment 1: Probability of Response

Proper manipulation of the probability of response requires identification of the behavioral unit that "demands" response. While in the "passive" or "listener" role, each participant in an interaction will emit a number of brief responses such as Rosenfeld's (1966) recognitions (e.g., smiles, head nods and shakes, gestures, facial expressions, brief utterances such as "I see," "Yeah," etc.), which provide important feedback for the other. Such responses have been variously termed "back-channel responses" (Duncan, 1975; Duncan & Fiske, 1977; Krauss, Garlock, Bricker, & McMahon, 1977; Yngve, Note 3), "listener responses" (Dittman & Llewellyn, 1967, 1968), "concurrent feedback" (Krauss & Weinheimer, 1966), or "signals of continued attention" (Fries, 1952). While the concept of responsiveness is intended to include such "back-channel" responses, because of the difficulty of identifying the unit of behavior that "demands" them, the present study dealt only with the probability of response at those junctures at which the exchange of the "active" (or speaker) role is demanded.

Under the guise of a study of the "acquaintanceship process," subjects exchanged information about themselves with another "subject" (actually a tape recording) by taking turns choosing and answering one of two questions on each of 6, 12, or 24 trials. Subjects were instructed to answer a question on each trial. However, they were told that their partner would be allowed to choose, for each trial, whether or not to answer a question. The tape responded for either 33% or 66% of the trials.

Table 1
Design of Experiment 1

Frequency of response	Probability of response	
	33%	66%
4	12 trials	6 trials
8	24 trials	12 trials

In the present situation, if the number of trials were held constant, probability and frequency of response would be confounded. Thus, differences in attraction as a function of probability of response, if obtained, could be interpreted as resulting from either differing amounts of information about the stimulus person (see Sloan & Ostrom, 1974) or different frequencies of exposure to him or her (e.g., to the sound of his or her voice; see Zajonc, 1968). In order to separate the effects of the two variables, probability (33% versus 66%) and frequency (4 versus 8) of response were factorially combined in the present experiment, while the number of trials varied between conditions.

Method

Subjects. Subjects were 96 Caucasian introductory psychology students, 48 males and 48 females, who participated for partial fulfillment of course requirements.

Design. In a 2 (probability of response) × 2 (frequency of response) × 2 (sex of subject) design, subjects chose and answered one of two questions on each of 6, 12, or 24 trials. Subjects were responded to on either 33% or 66% of the trials by a same-sex confederate's tape-recorded answer to the same question as that chosen by the subject. In order not to confound probability and frequency of response, the total number of trials was varied in relation to the two variables: In the 33% condition, the tape responded on either 4 of 12 or 8 of 24 trials; and in the 66% condition, the tape responded on either 4 of 6 or 8 of 12 trials. (The design of the experiment is illustrated in Table 1.)

Questions were designed to elicit information about the subject (e.g., "How do you usually spend summers?" "Do you keep house plants?" "What do you expect to be doing at 65?" "What would you do if you suddenly inherited a million dollars?" "Did you work during high school?" "Where do you spend most of your time outside of class?") and were designed to be neutral in content in order to minimize the effects of similarity.

The order of pairs of questions was Latin square counterbalanced for each condition. For the 6- and 12-trial conditions, the 24 pairs of questions were divided into four and two subgroups, respectively. The order of the 6 or 12 pairs was then Latin square counterbalanced within each subgroup, and each subject saw one of the orders within one of the subgroups.

Apparatus. The subjects' cubicle contained an intercom box approximately 60.96 cm wide × 30.48 cm high × 30.48 cm deep. Centered on its front were two panels labeled "Talk" and "Listen," and affixed to it were two buttons, one attached by wire and the other on the box under the "Talk" panel. The two buttons were used by the subjects to signal when ready to begin speaking and when finished speaking, respectively.

Subjects were instructed to signal when ready to begin speaking by pushing the button attached by wire. This, they believed, would cause the other's "Listen" panel to illuminate. When finished speaking, subjects pushed the panel button, which they believed would signal the other to begin by causing his or her "Talk" panel to illuminate. For the responsive trials, the panel button activated a control box in an adjacent room, which, after a fixed delay, caused the subject's "Listen" panel to illuminate and automatically initiated the appropriate taped response. For unresponsive trials, the experimenter pushed a button that caused the light to sequence back through the "Listen" panel to the "Talk" panel without activating the taped response.

Responses to the 48 questions were recorded separately on 96 cassette reels, 48 for a male and 48 for a female confederate. In this way, the experimenter could easily insert the appropriate tape after hearing the subject's choice of question. The tape was always an answer to the same question as the one chosen by the subject.

Procedure. Upon arrival, subjects were seated in a small cubicle containing an intercom system and a set of written instructions. The experimenter explained that another subject was expected, instructed the subject to read the written instructions, and left him or her to wait, closing the door behind him. After a brief delay, the experimenter pretended to lead another "subject" to the adjacent cubicle, audibly instructed the "subject" to read the instructions, and closed the door. The true subject's instructions were labeled "Instructions–Person A," and read as follows:

> This experiment is concerned with the acquaintanceship process as it occurs in brief encounters with another person, and as it occurs without the use of nonverbal cues such as physical appearance, dress style, eye contact, body posture, etc.
>
> You will be communicating with another person using the intercom system (the box in front of you). Both of you will have a booklet, with two questions on each page. You (Person A) will begin by choosing and answering one of the two questions on the first page of the booklet, and you will be required to answer one of the two questions on *all* of the trials.

You may begin your answer when the light is in the panel labeled "Talk." When you are ready to answer, push the button attached by wire to the box. This will activate the intercom and signal the other person that you are going to talk, by causing his or her "Listen" panel to illuminate.

Please begin by telling the other person which question you are going to answer (A or B), and then give your answer. When you have finished, push the red button under the "Talk" panel. This will signal the other person that you are finished by causing his or her "Talk" panel to illuminate.

Person B will then have the option of either responding or not responding on each trial. If Person B chooses to respond, when he or she is ready to talk, he (she) will push the button attached by wire to the box, again activating the intercom, and causing your "Listen" panel to illuminate. When finished, he or she will push the red button under the "Talk" panel, causing your "Talk" light to come on. If Person B chooses not to respond, he or she will just push the red button, and the lights will sequence back to your "Talk" panel.

Please do not communicate in any way other than by answering the questions.

The written instructions were accompanied by diagrams of the subject's own box and "Person B's" box, with further description of their operation.

When subjects had been allowed enough time to read the instructions, the experimenter opened both doors and, from the hallway facing the two cubicles, reviewed and elaborated upon the written instructions for the subject (Person A) and the nonexistent counterpart (Person B). Subjects were reminded that they were to answer on all trials, whereas their partner would have the option to respond or not on each trial. No explanation for this difference was offered. When the verbal instructions were complete, the experimenter instructed the subject to begin when the "Talk" panel illuminated, and closed both doors.

Upon completion of the trials, subjects responded to a questionnaire designed to assess their attraction to the confederate (eight items), perceptions of the confederate's attraction to them (two items), the degree to which they felt they and the confederate had become acquainted (two items), and their reactions to the experiment (two items). The questionnaire also included five items reflecting subjects' perception of confederate responsiveness and five filler items. Subjects also responded to a question designed to assess their awareness of the purpose of the experiment: "What do you think the experimenter expects to learn from the experiment?" "What was he interested in, and what were his hypotheses?" No subject guessed the purpose of the experiment. Subjects were debriefed by mail at the end of the semester.

Results

Attraction to confederate. It was predicted that subjects would like the confederate who responded on 66% of the trials better than the one who responded on only 33%. The postexperimental questionnaire included eight questions [1] designed to measure liking of the confederate (see Table 2). The first five columns of Table 2 indicate, respectively, the dependent measure of attraction and the means for the four treatment combinations.

The predicted main effect of probability of response was highly significant for seven out of the eight questions and in the predicted direction for the eighth. Columns 6 and 7 of Table 2 indicate the Fs and significance levels, respectively. Analysis of variance on the mean of the eight questions also yielded a significant main effect of probability of response, $F(1, 88) = 14.89$, $p < .001$.

There were no significant main effects of either sex or frequency of response, and in no case did probability of response interact with either variable.

Perceptions of confederate reactions to subject. Two of the postexperimental questionnaire items reflected subjects' perceptions of how much the confederate liked them ("How much do you think your partner likes you?") and the confederate's interest in their answers to the questions ("Did you think your partner was interested in the information you sent him/her?"). Although subjects tended to believe that the responsive confederate liked them more than the unresponsive one (Ms = 5.23 and 4.90, respectively) and that he or she was more interested in their answers to the questions (Ms = 4.40 and 3.71, respectively), the main effect of probability of response was only marginally significant for the two questions separately, Fs(1, 88) = 1.81 and 3.44, ps $< .17$ and $< .06$, respectively, and for their mean, $F(1, 88) = 3.67$, $p < .06$. Again, there were no significant effects involving frequency of response or sex.

Perceptions of acquaintanceship. Responsiveness affected the degree to which subjects felt that they and the confederate had become

[1] All questionnaire ratings were made on 11-point scales.

Table 2
Attraction to Confederate as a Function of Probability and Frequency of Response

Questionnaire item	Probability of response: 33% — Frequency of response: 4	33% — 8	66% — 4	66% — 8	Main effect, probability of response: $F(1, 88)$	p
How much do you like your partner?	5.31	5.71	6.38	6.63	12.89	.001
How well do you think you would get along with your partner?	5.08	5.00	6.17	6.63	14.85	.001
Were you interested in the information your partner sent you?	5.46	5.79	6.71	6.92	11.90	.001
How much would you enjoy a casual conversation with your partner, over a beer or coke?	6.21	5.38	7.08	6.96	12.72	.001
How much would you enjoy working on a problem with your partner?	5.08	5.42	6.63	6.29	11.70	.001
Is your partner the type of person you could become close friends with?	4.58	4.54	5.33	5.37	5.63	.02
Is your partner a good listener?	5.58	5.42	6.13	5.67	1.28	.26
How friendly is your partner?	5.63	5.92	6.79	6.46	4.97	.03
M	5.35	5.40	6.40	6.37	14.89	.001

Note. Ratings ranged from 0 ("not at all _____") to 10 ("very _____").

acquainted with one another. Responses to the postexperimental question "How well did you feel that you got to know your partner?" indicated that subjects felt they got to know the confederate who responded on 66% of the trials ($M = 4.09$) better than the one who responded on only 33% of the trials ($M = 3.16$); $F(1, 88) = 8.11$, $p < .005$.

In contrast, in response to the question "How well do you think that your partner got to know you?" subjects indicated that the confederate got to know them better in the 33% condition than in the 66% condition (Ms = 4.90 and 4.19, respectively), although the effect was only marginally significant, $F(1, 88) = 3.17$, $p < .08$. The latter effect is not surprising, however, since subjects answered twice as many questions in the 33% as in the 66% condition (i.e., for 12 and 24 versus 6 and 12 trials). In fact, the two 12-trial conditions did not differ from each other (4.83 versus 4.67), whereas the 6-trial condition was much lower (3.70) and the 24-trial condition higher (4.96).

Again, there were no main effects of either sex or frequency of response and no interactions of either variable with probability of response. It is interesting that frequency of response failed to affect the extent to which subjects felt that they had become acquainted with the confederate, despite the fact that they heard the confederate answer twice as many questions in the high frequency condition. On the other hand, probability of response did affect perceived acquaintanceship, even though the number of answers subjects heard from the confederate was constant across the two conditions.

Ratings of responsiveness. Five trait ratings reflected subjects' perceptions of confederate responsiveness. Again the main effect of probability of response was significant, indicating that responsive confederates (66% response) were perceived as more responsive, $F(1, 88) = 26.24$, $p < .001$; attentive, $F(1, 88) = 6.26$, $p < .02$; talkative, $F(1, 88) = 33.95$, $p < .001$; active, $F(1, 88) = 5.13$, $p < .025$; and sympathetic, $F(1, 88) = 3.80$, $p <$

.05, than the more unresponsive (33% response) confederate. There were no main effects of sex or frequency of response and no interactions of sex with probability of response for any of the above ratings. Although probability and frequency of response interacted for the trait "active," $F(1, 88) = 4.59$, $p < .04$, the two variables did not significantly interact for the other four ratings.

Differences in number of trials. In order to independently manipulate probability and frequency of response, the number of trials varied between conditions (see Table 1). The two 33% conditions involved 12 and 24 trials, whereas the two 66% conditions involved 6 and 12 trials. The effect of probability of response may be tested, however, while holding the number of trials constant.

T tests were performed to test the difference between the two cells involving 12 trials (frequency = 4, probability = 33% versus frequency = 8, probability = 66%) on the means of the three major dependent variable categories. The comparison was significant for all three: attraction to the confederate, $t(46) = 14.48$, $p < .001$; perceptions of confederate attraction to the subject, $t(46) = 9.88$, $p < .001$; and the degree to which subjects felt they got to know the confederate, $t(46) = 15.96$, $p < .001$.

Although probability and frequency of response are confounded for the above comparison, it is doubtful that differences in frequency of response accounted for the results. The overall main effect of frequency of response was not significant, and for the other possible comparison (frequency = 8, probability = 33% versus frequency = 4, probability = 66%) the means were in the opposite direction (i.e., frequency of response was inversely related to the three dependent variables). The failure of frequency of response to affect attraction is, of course, consistent with existing evidence that attraction varies with the proportion, but not number, of positive reinforcers (e.g., Byrne & Nelson, 1965).

Discussion

The results of Experiment 1 are clearly consistent with the hypothesis that attraction will vary positively with responsiveness. Subjects liked the confederate who responded on 66% of the trials more, believed that he or she liked them more, and felt that they got to know him/her better than the confederate who responded on only 33% of the trials. However, since only related responses were employed (the confederate always answered the same question as the subject), there is no direct evidence that the effect of probability of response would hold for unrelated responses as well. Indirect evidence is available, however, through comparison of the present results with those of Experiment 2, which will be described in the general discussion of the two experiments.

Experiment 2: Proportion of Related Responses

Experiment 2 was designed to test the hypothesis that attraction will be a positive function of the proportion of related responses. As in Experiment 1, subjects exchanged information about themselves with another subject (actually a confederate) by taking turns choosing and answering questions about themselves. The subject and confederate chose one of three questions on each of 10 trials. Relatedness was varied through the confederate's choice of question. He or she chose either the same question as the subject (related response) or one of the two different questions (unrelated response). The same question was chosen on either 80% or 20% of the trials.

For half of the subjects, the confederate answered after the subject on each trial, in which case his or her choice could be perceived as a response to the subject's answer. For the other half, in order to control for the possibility that perceived similarity (as a result of choosing the same questions) could affect attraction, the confederate answered first. In this case, his or her responses could in no way be perceived as contingent upon those of the subject and, thus, could not be perceived as a response to the subject. Therefore, for the confederate-first condition, the proportion of related responses should not affect attraction.

Method

Subjects. Subjects were 80 Caucasian introductory psychology students, 40 males and 40 females, who

participated for partial fulfillment of course requirements.

Design. In a 2 (sex of dyad) × 2 (order) × 2 (proportion of related responses) factorial design, subjects and a same-sex confederate[2] alternately chose and responded to one of three questions on each of 10 trials. Using prearranged responses, the confederate answered the same question as the subject on either 80% or 20% of the trials. For half of the subjects, the confederate answered first on all 10 trials, and for the other half, the subject answered first for the 10 trials.

As in Experiment 1, questions were designed to elicit information about the subject (e.g., "What did you do the last time it was a nice day?" "What family traditions do you have around holidays?" "What are your parents' occupations?" "What mode of transportation do you use to get around town?" "What classes are you taking this semester?") and to be neutral and noncontroversial in content. In addition, the three questions for each trial were scaled and equated for intimacy level.

The order of the 10 triads of questions was Latin square counterbalanced, and the two responses that represented the 20% (either same or different) always occurred on Trials 2 and 8.

Procedure. Upon arrival, subjects were seated in a small cubicle containing an intercom system. The experimenter explained that another "subject" was expected and left the subject to wait, closing the door behind him. After a brief delay, another "subject" (actually a same-sex confederate) was audibly led to the adjacent cubicle. The experimenter then opened both doors and instructed both subject and confederate from the hallway facing the two rooms. At no time during the experiment did the subject and confederate come into visual contact.

Subjects were told that the purpose of the experiment was to study the "acquaintanceship process" as it occurs through the exchange of information alone, without the use of the physical and nonverbal cues normally present in everyday interactions. The experimenter explained that in this case, the participants would be communicating over the intercom system and getting acquainted simply by taking turns answering questions about themselves.

Both subject and confederate were given a 10-page booklet containing three questions per page and were instructed to take turns choosing and responding to *one* of three questions available on each of the 10 trials. The experimenter explained that they should begin each turn by announcing which question they were going to answer and signal when finished by saying "OK." It was stressed that conversation should be strictly confined to answering the questions. No other conversation, such as extraneous questions or comments, was permitted.

For the confederate-first condition, in order for the confederate to make the appropriate number of "same" responses, subjects were instructed to choose and indicate their choice of questions on a "choice form," which was collected by the experimenter before the trials began and used to choose the confederates' responses. Subjects also circled their choices on their own booklets, and the experimenter stressed that they were not to alter their choices after the experiment began. Subjects believed that the same procedure was followed by the confederate.

This procedure was employed in order to ensure that for the confederate-first condition, the confederate's choices would not be perceived as contingent upon those of the subject. In the subject-first condition, choice forms were not employed, and both the subjects' and confederates' responses were chosen as the trials progressed.

When the instructions and the choice forms (for the confederate-first condition) were complete, the experimenter allowed the subject and confederate to greet each other in order to become familiar with the intercom system, instructed either the subject or the confederate to begin, and closed both doors.

To keep the confederate blind to condition, a visual cue from the experimenter, who was monitoring the subject's responses via headphones located in the confederate's cubicle, informed the confederate when, and to which question, to give the prearranged response.[3]

Upon completion of the trials, subjects completed the same questionnaire as the one employed in Experiment 1, and again were debriefed by mail at the end of the semester.

Results

Attraction to confederate. It was hypothesized that the proportion of related responses would influence attraction in the subject-first condition, but not in the confederate-first condition. Again, the postexperimental questionnaire included eight questions designed to measure liking of the confederate (see Table 3). The first five columns of Table 3 indicate, respectively, the dependent measure of attraction and the means for the four treatment combinations.

The predicted interaction of order with

---

[2] One confederate of each sex was employed.

[3] If there tended to be distinct patterns for subjects' choices among the three questions for the 10 triads, then there would also be distinct patterns for the questions answered by the confederate. In other words, subjects who answered with 80% related responses would typically answer different questions than those who responded with 80% unrelated responses. Differences in attraction might then be explained by differences in questions answered by the confederate. In order to examine this possibility, the experimenter kept a record of all subject and confederate choices. Analyses of this record indicated that subjects chose all questions approximately equally often and that confederate choices did not differ across conditions.

proportion of related responses was statistically significant for six of the eight questions (see column 6 of Table 3) and for the mean of the eight questions, $F(1, 72) = 8.78$, $p < .004$. For the other two questions, the interaction failed to reach significance by only a small margin.

The simple effect tests for proportion of related responses within the subject-first and confederate-first conditions (columns 7 and 8 of Table 3) indicated that as predicted, related responses facilitated attraction when the subject answered first, but did not significantly affect attraction when the confederate answered first. There were no interactions involving sex for any of the questionnaire items.

Perceptions of confederate reactions to subject. Two of the postexperimental questionnaire items reflected subjects' perceptions of how much the confederate liked them and the confederate's interest in their answers. Again, the proportion of related responses interacted with order, such that when subjects answered first, they believed that a confederate who answered the same question on 80% as opposed to 20% of the trials liked them more (Ms = 6.55 and 5.55, respectively), simple $F(1, 72) = 5.05$, $p < .03$, and was more interested in their answers (Ms = 6.45 and 4.40, respectively), simple $F(1, 72) = 13.54$, $p < .001$; but when the confederate answered first, the proportion of related responses had no effect, Fs$(1, 72) < 1.53$, *ns*. The interaction was significant for both questions, Fs$(1, 72) = 6.07$ and 8.15, ps $< .02$ and $< .006$, respectively, and for their mean, $F(1, 72) = 6.59$, $p < .01$.

Perceptions of acquaintanceship. The proportion of related responses affected the extent to which subjects felt that they and the confederate became acquainted with one another and the extent to which they enjoyed the experiment, again only in the subject-first condition. When subjects answered first, they felt that they got to know the confederate better (Ms = 6.60 and 4.95), simple $F(1, 72) = 8.07$, $p < .006$, and that the confederate got to know them better (Ms = 6.30 and 4.45), simple $F(1, 72) = 11.73$, $p < .001$, when the confederate answered the same question for 80%, as opposed to 20%, of the trials. There were no significant differences for the confederate-first condition. The interaction was significant for both questions, (Fs$(1, 72) = 5.35$ and 5.86, ps $< .03$ and $< .02$, respectively).

Similarity. Neither order nor the proportion of related responses affected subjects' ratings of their partner's similarity to themselves. This result, in combination with the absence of an effect of relatedness for the confederate-first condition, argues against the alternative explanation of the results that the proportion of related responses affected attraction through its effect on perceived similarity.

Ratings of responsiveness. Subjects rated the confederate as more "responsive" when he or she answered 80% of the same questions rather than 20%, $F(1, 72) = 3.49$, $p < .07$, but only for the subject-first condition, interaction $F(1, 72) = 3.21$, $p < .08$. These effects were only marginally significant, however, and responsiveness did not affect ratings of "attentive," "talkative," "active," and "sympathetic," as it did in Experiment 1. This difference probably occurred because subjects' personal definitions of these adjectives are more tied to probability than to relatedness of response.

General Discussion

The results of the two experiments clearly supported the hypothesis that attraction is facilitated by responsiveness. For Experiment 1, probability of response facilitated attraction, as well as the perception of acquaintanceship with the confederate. Subjects also tended to believe that the confederate who responded with high probability liked them more and was more interested in their answers to the questions than the one who responded with low probability.

For Experiment 2, those in the subject-first condition not only liked the confederate who gave 80% related responses more, but also felt that the confederate liked them more and was more interested in their answers and that the two of them had become better acquainted with one another. These results are especially impressive, given the large amount of information (constant across conditions) that

Table 3
Attraction to Confederate as a Function of Order and Proportion of Related Responses

Questionnaire item	Order: Subject first, Proportion of related responses 80%	Order: Subject first, Proportion of related responses 20%	Order: Confederate first, Proportion of related responses 80%	Order: Confederate first, Proportion of related responses 20%	Interaction of Order × Proportion of Related Responses $F(1, 72)$	Interaction of Order × Proportion of Related Responses p	Simple effects proportion of related responses: Within subject-first condition $F(1, 72)$	Within subject-first condition p	Simple effects proportion of related responses: Within confederate-first condition $F(1, 72)$	Within confederate-first condition p
How much do you like your partner?	7.40	6.80	7.25	7.95	4.19	.04	1.79	.18	2.43	.13
How well do you think you would get along with your partner?	6.55	5.90	6.70	7.55	3.51	.07	1.32	.25	2.25	.14
Were you interested in the information your partner sent you?	7.70	6.50	7.25	7.70	4.16	.05	4.40	.04	<1	.44
How much would you enjoy a casual conversation with your partner, over a beer or coke?	7.95	6.85	7.20	7.85	5.09	.03	4.02	.05	1.41	.24

M	7.42	6.33	7.11	7.79	8.78	.004	6.43	.02	2.74	.10

Note. Ratings ranged from 0 ("not at all _____") to 10 ("very _____").

was conveyed by the confederate's answers to the 10 questions and by his or her style of verbal interaction—information that would doubtless carry a great deal of weight for impressions formed of the confederate. It is also impressive that responsiveness affected attraction in the present situation, where relevant responses should not have been necessarily expected or demanded by the situation, and where unrelated responses would not reflect negatively upon the character of the confederate.

As mentioned earlier, since Experiment 1 employed only related responses, there was no direct evidence that the effect of probability of response would hold for unrelated responses. The subject-first, 20% related condition of Experiment 2 represents a comparison in which the probability of *related* response was even lower (20%) than for the low-probability-of-response (33%) condition in Experiment 1. Despite the fact that the former condition involved lower probability of related responses, attraction to the confederate ($M = 6.33$), perceptions of confederate attraction to the subject ($M = 4.98$), and the degree to which subjects felt that they had gotten to know the confederate ($M = 4.95$) were greater than the comparable values for the 33% response condition of Experiment 1 (Ms = 5.38, 4.30, and 3.13, respectively). While comparisons between experiments are tenuous, it is plausible to argue that the differences were due to the relative probabilities of *unrelated* responses (80% versus 0%).

Perceived Acquaintanceship

Perhaps one of the most interesting results of the two experiments was the relationship between responsiveness and perceived acquaintanceship. For Experiment 1, probability of response affected the degree to which subjects felt that they became acquainted with the confederate, even though the number of answers they heard from the confederate was constant across the two conditions. Frequency of response, on the other hand, did not affect perceived acquaintanceship, despite the fact that subjects heard the confederate answer twice as many questions in the high frequency condition. For Experiment 2, the proportion of related responses affected perceived acquaintanceship: Subjects felt that they became better acquainted with the confederate and that the confederate had become better acquainted with them when the confederate responded with 80% related answers. Apparently, responsiveness affected something more basic than attraction, namely, the perception of a "bond" or "relationship" between the subject and confederate.

Literature on pathological communication (e.g., Danziger, 1976; Laing, 1961; Ruesch & Bateson, 1951; Sluzki et al., 1967; Watzlawick et al., 1967) suggests that the relationship between the successive communicative acts in an interaction serves to define the relationship between the participants. As long as a response addresses the content of the preceding message—whether positively, negatively, with agreement or disagreement—it is assumed to provide confirmation of the other as a person. In contrast, an irrelevant response or failure to respond—a "disqualification"—is assumed to communicate the interpersonal message "You do not exist." Danziger (1976) has expressed the point well:

> In recognizing the meaning and intent of a message and addressing myself to its implied demand I also recognize the originator of the message as a person. In disqualifying a message and refusing to recognize its nature I invalidate the claim to self-definition that it implies. If I show by my inappropriate response that a message has not registered I am at that moment refusing confirmation of the personality that is the source of the message. (p. 139)

Certainly, in order to "get to know" an individual, one must first recognize his or her claim to personhood. It may be that for the present studies, responsiveness communicated to the subject that the confederate was reacting to him or her as a person, thereby inducing the perception of greater acquaintanceship. At the least, the data indicate that responsiveness communicated to the subjects that the confederate liked them and was interested in their answers to the questions.

The results for the confederate-first condition in Experiment 2 attest to the importance of the perception of contingency between the responses, both for the definition of the relationship (or the perception of acquaintanceship) and for attraction. Since the responses

were chosen before the interaction began, and since the subject answered after the confederate, the confederate's responses could not have been perceived as responses to the subject and consequently could not have been interpreted as a comment on their "relationship." Thus, not surprisingly, the proportion of related responses affected neither attraction to the confederate, nor subjects' perceptions of how much the confederate liked them, nor the degree to which subjects felt that they and the confederate became acquainted with one another.

A final piece of evidence concerning the importance of related responses came from pilot subjects in the confederate-first 20% related condition. Until the instructions were modified to strictly and redundantly forbid that the choice of questions be altered during the interaction, subjects frequently changed responses that should have been different from the confederate's in order to answer the same question. When confronted, they complained, "But how can we get to know each other if we just keep answering different questions that have nothing to do with each other?" Apparently, subjects felt that it was necessary to *be* responsive in order to become acquainted with the other person.

Implications for Self-Disclosure Research

Research on self-disclosure (e.g., Altman, 1973; Altman & Taylor, 1973) has been concerned with the content (i.e., intimacy level) of information exchanged in dyadic interaction. The present analysis suggests that the sequential *process* of disclosure may be as important as the specific content. As suggested above, greater feelings of acquaintanceship and attraction, as well as greater perception of control, will develop from interactions in which each participant's responses address the content of the other's preceding communication. Thus, it would be expected that those disclosures which most directly address previous disclosures or other behaviors of the perceiver will produce greatest attraction.

The majority of self-disclosure research has focused on the absolute intimacy level of another's disclosures, independently of the perceiver's own. However, it may be argued that disclosures at the *same* level of intimacy will be perceived to be directly related to the preceding communication with greater probability than those at a different level of intimacy. It may also be argued that one will feel more in control of the intimacy level of the interaction to the extent that another's disclosures are of the same level of intimacy as one's own. If so, another will be more attractive the more closely his or her disclosures *match* the intimacy level of the perceiver's.

Directions for Future Research

Although the results of the present two experiments were clearly consistent with the hypothesis that attraction is facilitated by responsiveness, the experimental interactions were highly structured and in many ways quite different from more naturalistic interaction. Both the format of the interaction (i.e., taking turns answering questions) and the range of alternative responses (choice among two or three topics) were defined by the experimenter. In addition, unresponsiveness was specifically condoned by the experimenter. For Experiment 1, the confederate was told that he or she could choose not to respond, and for Experiment 2, that he or she could answer any of the three questions. Because of the structure of the situation, the attributions resulting from the confederate's unresponsiveness—both regarding his or her social graces and his or her feelings toward the subject—should have been less extreme than those concerning unresponsiveness in more naturalistic interactions. Responsiveness should also have been less related to maintenance of interaction, predictability, control, stress, and facilitation of interaction goals in the present situation. Thus, one of the first priorities of future research should be to manipulate responsiveness in the context of less structured more naturalistic interactions, where it would be expected to have even greater impact on attraction.

Given the importance of responsiveness for human interaction, future research might also profitably explore the determinants of two persons' capacity for mutually responsive interaction. At least five conditions are necessary for

responsive interaction. In order to be responsive, one must first attend to the other person, both in order to detect behaviors that demand response and in order to process those behaviors with sufficient accuracy to be able to respond with related content. Many situational characteristics, such as other persons present, task demands, noise, or other distracting stimuli, will affect the degree to which attention is available for the person with whom one is interacting. Internal demands for attention, such as self-consciousness, preoccupation with irrelevant thoughts or with bodily sensations, and so forth will also reduce attention to the other person. Finally, stimulus characteristics of the other person may influence the amount of attention devoted to him or her. It is reasonable to assume, for example, that one will devote more attention to those whom one likes, those who are of high status or in control of rewards, or those who are physically attractive.

A second condition necessary for responsive interaction is the motivation to be responsive. Responsiveness has two effects, which may or may not be desirable to the participants: (a) It tends to prolong the interaction and (b) it tends to lead the participants to feel more of a relationship (or more intimacy) with one another. If either or both of the two effects are undesirable to the participants, the motivation to be responsive will be correspondingly low. As Watzlawick et al. (1967) have pointed out, unrelated or irrelevant responses (disqualifications) are commonly employed as a means to either terminate an interaction or to change the subject. Thus, the motivation to be responsive should be affected by such factors as the attractiveness of the other person and the degree to which he or she controls rewards, as well as by temporary factors affecting the desire to interact at a specific time or place or on a particular topic.

Given that a person has attended to the other and is motivated to be responsive, he or she must have the capacity or energy to respond at the rate "demanded" by the other. When interacting with another who talks rapidly and at length, one must have the energy to respond rapidly and at length. If the "interaction rates" of two persons are not matched, the more active participant will feel frustrated by the other's unresponsiveness, while the less active participant will feel drained by the constant demand for response. Chapple (1939, 1974) has argued for years that two persons' capacity for smooth interaction will be determined in part by the match of their activity levels. Similarly, Latané and Hothersall (1972) have argued that the relative preference of rodents for within- versus between-species others results in part from incompatible activity levels, or "interaction rates," between species.

In order to respond with related content, one must first accurately interpret the meaning of the other person's behavior or communication. Accuracy of understanding will be affected, in part, by the content of the communication. The more ambiguous the subject matter, the more difficult it will be to interpret accurately, and therefore the less responsive will be the interaction. The cognitive skills of the participants will also affect the capacity for responsive interaction. The ability to accurately understand communications will be determined both by general verbal skills and by the ability to take on the frame of reference of the other person. Thus, the capacity for responsiveness will increase with the intelligence, general knowledgeability, cognitive development, and cognitive complexity of the participants, and with their familiarity with one another.

Understanding will also be facilitated by many forms of similarity. It would be expected, for example, that any shared characteristic (such as race, culture or subculture, socioeconomic class, profession, interests, cognitive structure, and even shared experience) that would lead two persons to share ways of thinking or of perceiving the world, of using language, or of interpreting behavior would facilitate understanding and therefore responsiveness. Similarity of culture (Triandis, 1964, 1975), socioeconomic class (Harms, 1961), and cognitive structure (Runkel, 1956; Shibuya, 1962; Triandis, 1959, 1960a, 1960b) have, in fact, been shown to facilitate communication.

The fifth, and final, condition necessary for responsive interaction is that the participants

possess the response repertoire necessary for related responses. Again, similarity, as well as general knowledgeability, will be important. Since persons most often initiate conversations dealing with topics in which they are interested or knowledgeable, or with which they are currently concerned, persons who share similar interests, knowledge, or topics of concern will more often engage in responsive interaction than those who do not.

Conclusions

The present demonstration of the importance of responsiveness illustrates the utility of exploration of interaction-based determinants of attraction. Such sequential response contingencies as those described here may be profitably explored as both independent and dependent variables, as illustrated above. As a dependent variable, responsiveness or other sequential response contingencies may allow identification and greater understanding of variables that may influence attraction either partially or entirely through their influence on interaction (e.g., similarity).

Behavioral Change in a Constant Environment: Shift to More Difficult Tasks With Constant Probability of Success

Julius Kuhl
Ruhr University, Bochum, West Germany

Virginia Blankenship
University of Michigan (Ann Arbor)

The present experiment was designed as a first attempt to test hypotheses derived from Atkinson & Birch's dynamic theory of action, which proposes a theoretical reorientation from an *episodic* to a *dynamic* view of motivation. Traditional episodic theories of achievement motivation predict constant risk preference over a series of free choices from various difficulty levels when the assumed situation-specific determinant (probability of success) remains constant. In contrast to this, the dynamic theory predicts a shift to more and more difficult tasks, both for success-oriented and for failure-oriented subjects. In addition, the dynamic theory predicts that the initial ambivalence between very easy and very difficult tasks, predicted by traditional theory of achievement motivation for failure-oriented subjects, is quickly replaced by a consistent preference for very easy tasks in that motive group. The results of the present experiment support the predictions derived from the dynamic theory.

When subjects are allowed to choose tasks from a given set of different difficulty levels over an extended period of time, a shift of preference to more and more difficult tasks is the common finding (e.g., Atkinson, Bastian, Earl, & Litwin, 1960; Atkinson & Feather, 1966). The cognitive theory of achievement motivation (Atkinson, 1957; Atkinson & Feather, 1966; Raynor, 1969) and its reformulation within an attributional theory of motivation (Heckhausen, 1973, 1977; Weiner et al., 1971) attribute such shifts in risk preference to respective changes in the relevant situation-specific determinant of risk preference, namely, subjective probability of success. According to this hypothesis, subjects move to more difficult levels during a series of free choices among various difficulty levels because subjective probability of success increases as a result of subjective improvement. With probability of success held constant, no systematic shift in preferred difficulty would be expected. In recent years, a dynamic theory of motivation has been developed that explains behavioral change even if the situation-specific determinants remain constant (Atkinson & Birch, 1970, 1974). The experiment to be described here was designed to test this hypothesis, which was derived from *The Dynamics of Action* (Atkinson & Birch, 1970), stating that shifts to more and more difficult tasks occur even if subjective probability of success is held constant (i.e., has stabilized after a sufficiently long practice period).

This article was prepared during an exchange visit granted to the first author by the German Science Foundation.

The authors wish to thank John W. Atkinson for numerous helpful suggestions and Marjan Kuhl-de Heus and Glenn Gallop for serving as assistant experimenters.

Requests for reprints should be sent to Virginia Blankenship, Department of Psychology, University of Michigan, Ann Arbor, Michigan 48109.

The Dynamics of Action

The basic concepts and assumptions of this theory (Atkinson & Birch, 1970, 1974) are

Copyright 1979 by the American Psychological Association, Inc. 0022-3514/79/3704-551$00.75

summarized in a recent article on computer simulation of imaginative behavior (Atkinson, Bongort, & Price, 1977):

> If a certain kind of activity has been intrinsically satisfying or previously rewarded in a particular situation, there will be an *instigating force* (F) for that activity, attributable in part to strength of motive in the person and in part to the magnitude of incentive for that activity in that situation. This will cause a more or less rapid arousal and increase in the strength of an inclination to engage in that activity, an *action tendency* (T), depending on the magnitude of the force. If a certain kind of activity has been frustrated or punished in the past, there will be an *inhibitory force* (I) and a more or less rapid growth in the strength of a disinclination to act. This is what we now call a *negaction tendency* (N) and conceive as a tendency *not* to do it. The duration of these forces will determine how strong the action tendency or negaction tendency becomes. The latter, the tendency not to do something, will produce *resistance* to the activity. It opposes, blocks, dampens; that is, it subtracts from the action tendency to determine the *resultant action tendency* ($\bar{T} = T - N$). The resultant action tendency competes with other action tendencies for other incompatible activities. The strongest of them is expressed in behavior. The expression of an action tendency in behavior is what reduces it. Engaging in activity produces a *consummatory force* (C), which depends in part on the consummatory value (c) of the particular activity and in part on the strength of tendency being expressed in behavior (i.e., $C = c\bar{T}$). Similarly, the resistance to an action tendency, produced by the opposition of a negaction tendency, constitutes an analogous *force of resistance* (R), which reduces, in a comparable way, the strength of the negaction tendency.

The force of resistance (R) is a function of the negaction tendency and the resistance value (r) of the particular activity (i.e., $R = r \cdot N$). In order to derive predictions from the theory concerning changes in risk preference during a series of free choices among various difficulty levels, definitions have to be made coordinating the basic parameters (F, I, c, and r) to the assumed antecedents in achievement-related situations.

Coordinating Definitions

The instigating force (F_i) to choose Difficulty Level i is defined by the product of the motive to succeed (M_S), the subjective probability of success (P_{s_i}), and the incentive value of success (I_{s_i}), which is considered the complement of P_s ($I_s = 1 - P_s$):

$$F_i = M_S \times P_{s_i} \times (1 - P_{s_i}). \quad (1)$$

Equation 1 differs from the original theory of achievement motivation (Atkinson, 1957; Atkinson & Feather, 1966) in relating the product of motivational determinants to a parameter controlling the *rate of increase* (F_i) rather than the absolute strength (T_i) of a motivational tendency (cf. Atkinson & Birch, 1970, 1974).

Similarly, the inhibitory force (I_i) controlling the rate of increase in the tendency to avoid working on Difficulty Level i is defined as

$$I_i = M_F \times (-P_{s_i}) \times (1 - P_{s_i}), \quad (2)$$

where M_F describes the motive to avoid failure.

Consummatory value (c), that is, the rate of reduction in the tendency to continue choosing a given level of difficulty, is assumed to be greater for success than for failure ($c_s > c_f$). This is consistent with results obtained by Weiner (1965) showing that for success-oriented subjects, level of performance and persistence are greater following failure than following success. The average consummatory value ($\bar{c}$) in a series of repeated attempts at the same level of difficulty may be assumed to be a function of the *objective* probability of success (p_s):

$$\bar{c} = c_s \cdot p_s + c_f \cdot p_f. \quad (3)$$

In the experiment to be described below, objective and subjective probability of success are assumed to be identical.

Similarly, it is assumed here that the resistance value (r), which controls the reduction of negaction tendencies, varies as a function of success and failure. A plausible theoretical assumption would be that resistance as a result of fear of failure is reduced after success to a greater extent than after failure. This is consistent with results suggesting that failure-oriented subjects show better performance and greater persistence after success than after failure (Weiner, 1965). The average force of resistance ($\bar{r}$) in a series of repeated attempts at the same difficulty may be assumed to be a function

of the objective probability of success (p_s):

$$\bar{r} = r_s \cdot p_s + r_f \cdot p_f. \quad (4)$$

Computer simulations of the dynamic theory using Equations 3 and 4 for defining average c and r values, respectively, resulted in predictions that were equivalent to those obtained in trial-by-trial simulations using the appropriate c_s or c_f value after each success or failure outcome, respectively (Kuhl & Blankenship, in press). It was concluded from this result that Equations 3 and 4 may be used to derive predictions from the dynamic theory.

Predicted Change in Risk Preference

Equations 1 to 4 may be used to derive predictions concerning changes in risk preference in a series of free choices from a given set of different difficulty levels. Though mathematical derivations are not possible because of the complexity of the theory and the situation it is applied to, the implications of the theory for a given situation may be found by computer simulations of the theory. Simulations of the dynamics of action yielded the following hypotheses when the basic parameters (F_i, I_i, c_i, r_i) were defined as suggested by Equations 1 to 4. A description of the simulation program (Bongort, Note 1), the simulation procedure, and the simulated results can be found elsewhere (Kuhl & Blankenship, in press).

Hypothesis 1. For success-oriented subjects ($M_S > M_F$), the slope of the regression line describing preferred difficulty ($1 - P_s$) as a function of time (trials) is greater than zero, indicating a gradual shift to more difficult tasks.

Hypothesis 2. The intercept of this regression line does not differ from the intermediate difficulty level ($P_s = .5$). This indicates a preference for intermediately difficult tasks ($P_S = .5$) at the first trial when $M_S > M_F$.

Hypothesis 3. For failure-oriented subjects ($M_F > M_S$), the slope of the regression line describing preferred difficulty ($1 - P_s$) as a function of time (trials) is greater than zero, indicating a gradual shift to more and more difficult tasks.

Hypothesis 4. The intercept of this regression line is at a difficulty level lower than the intermediate one ($P_s > .5$). This indicates a preference for tasks easier than intermediately difficult at the first trial when $M_F > M_S$.

Hypothesis 5. For subjects with low motivation ($M_S \approx M_F$), the slope of the regression line describing preferred difficulty ($1 - P_S$) as a function of time (trials) does not differ significantly from zero.

Hypothesis 6. The mean slope of the regression line is greater for success- than for failure-oriented subjects.

These simulated predictions were confirmed by trial-by-trial simulations using specific c_s or c_f values after each success or failure outcome rather than average c and r values based on Equations 3 and 4.

Initial Risk Preference

Hypothesis 2 corresponds to the well-known implication of the original theory of achievement motivation: Success-oriented subjects prefer intermediately difficult tasks (Atkinson, 1957). For failure-oriented subjects, the simulations of the dynamics of action yielded ambivalence between the easiest and the most difficult task (Kuhl & Blankenship, in press), as predicted by the original theory (Atkinson & Feather, 1966). This prediction, however, described the very first trials only. After the first few trials, a clear-cut preference for the easiest difficulty level is predicted—because of the reduction of negaction tendency, which is assumed to be greater for easier than for more difficult tasks when $r_s > r_f$ (Equation 4). Since the hypotheses are based on the assumption of stabilized P_s values, a practice period is necessary before the beginning of the main phase of the experiment. Hypothesis 4 states the prediction for the main phase, assuming that the short period of ambivalence between extreme difficulty levels has already been finished during the practice period (Kuhl & Blankenship, in press).

Temporal Change in Risk Preference

Hypotheses 1 and 3 contain the main implications to be tested in this experiment.

In contrast to the original theory, a shift to more and more difficult tasks is predicted for both success- and failure-oriented subjects even when P_s is assumed to have stabilized at the end of the practice period. This is explained as a result of consummation, which is assumed to be greater at easy than at more difficult tasks when $c_s > c_f$ (Equation 3). Hypothesis 3 is also in contrast to predictions derived from a recent application of some concepts of the dynamics of action (Revelle & Michaels, 1976). Based on a mistaken interpretation of the coordinating definitions made in the dynamics of action (Atkinson & Birch, 1970), Revelle & Michaels (1976, p. 396) predict that failure-oriented subjects will show a strategy that is the reverse of what is expected from success-oriented subjects (Kuhl & Blankenship, in press). According to the dynamics of action, failure-oriented subjects show—like success-oriented subjects—a trend to increasingly more difficult tasks, because resistance due to negaction tendencies is more quickly reduced for easier tasks than for more difficult tasks (cf. Equation 4). As a result, a tendency to choose more and more difficult tasks will emerge, after a delay that is proportional to the time required to overcome initial resistance.

Forced Choice

Revelle & Michaels's discussion of a special case of the dynamics of action is based on the assumption of continuous operation of consummatory forces, as if a subject is working on all difficulty levels at the same time. This is, of course, an unrealistic assumption for a situation in which a person makes a choice of one among tasks that differ in difficulty. The ideal case of working on all difficulty levels at the same time can be approximated, however, by forcing the subject to work successively on all difficulty levels included in the experiment before repeating the series. Such a "forced-choice" situation is introduced in the experiment described below.

For this experimental condition, the dynamics of action as well as Revelle & Michaels's special case derived from it predict a trend to increasingly more difficult tasks provided initial tendency strengths (T_i) are close to zero. When a considerable number of practice trials precede the main phase of the experiment, however, both theories predict this trend to weaken to the extent that T_is approach the respective asymptotic levels. This change in trend can be seen from Figure 1, which is based on a computer simulation of the forced-choice condition using initial tendency strengths markedly above zero. These predictions are in contrast to what is expected for the free-choice condition: Computer simulations showed that in this situation, the dynamics of action predict the trend to more difficult tasks, both when T_is are close to zero and when T_is are close to the respective (F/c) value (asymptotic level; Kuhl & Blankenship, in press).

The reason for this implication of the theory seems to be related to a positive-feedback effect typical of the free-choice condition. Under free-choice conditions, the strength of a tendency rises considerably higher than the asymptotic level it would approach if the expression of any competing tendency were prevented: Whenever a tendency is in the "dormant" state (i.e., another tendency has gained dominance), it is no longer a function of consummatory force (the necessary determinant of its asymptotic level in the dormant state) and may, as a result, rise above its asymptotic level if the latter is lower than the momentary strength of the dominant tendency. In sum, the dynamics of action predict a stronger trend to more difficult tasks in the free-choice than in the forced-choice condition, whereas Revelle & Michaels's (1976) theory predicts no such interaction, since it is limited to the forced-choice paradigm.

Method

Subjects

Forty male and 37 female subjects were obtained from the introductory psychology course at the University of Michigan (Ann Arbor) during the 1976 fall semester. Participation in a psychology experiment was a requirement of the course. All 77 subjects were tested in group sessions. Of these, 64 subjects (32 males, 32 females) were sub-

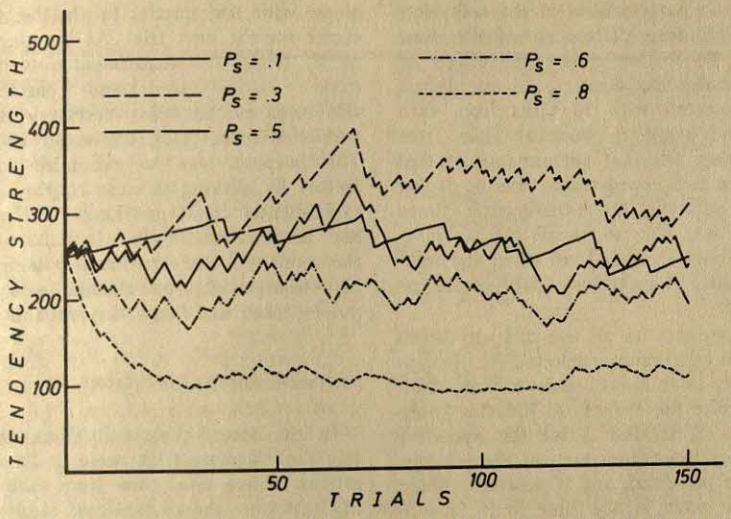

Figure 1. Simulated choice tendencies for the five probability of success (P_s) levels for a forced-choice situation.

sequently selected at random and assigned at random to the two experimental groups for individual testing.

Group Sessions

The two experimenters administered a Thematic Apperception Test (TAT; McClelland, Atkinson, Clark, & Lowell, 1953) using sex-specific verbal cues following Horner (1974) and a short form of the Test Anxiety Questionnaire (TAQ; Mandler & Sarason, 1952) in three group sessions that varied in size from 19 to 29 subjects. The TAT Need for Achievement Scale (n Ach) was administered with standard neutral instructions.

Individual Sessions

Instructions for both experimental groups (forced choice and free choice) were the same in the first part of the individual sessions. The subjects were told that it was the purpose of the experiment to get information about how people feel about a new series of tasks. In order to give knowledgeable answers, they would have to work on a series of these tasks first. Subsequently, subjects were instructed in the task, which was a modified version of a perceptual reasoning task used by Feather (1963). Figure 2 illustrates an example of the task, which had been studied extensively by Kuhl (1977). The objective of the task is to connect the numbered dots in order with an imaginary line starting at the arrow and proceeding to the highest-numbered dot. The correct answer to the task is the number of units (line segments) in the shortest line that will connect the dots in sequential order without violating any of the following rules: (a) The line may not cross, touch, or retrace itself. (b) The borderline of the grid may not be touched or traced. (c) Only the lines within the grid may be traced. Subjects were told that the tasks were similar to items on typical IQ tests and that their opinions were being sought concerning the difficulty of the tasks, problems they saw regarding the tasks, and so on, which would be elicited on a questionnaire to be administered at the end of a prolonged session during which the subjects would gain sufficient familiarity with the tasks.

One puzzle from each difficulty level was solved verbally by the subjects so that the experimenter could check the subjects' understanding and appli-

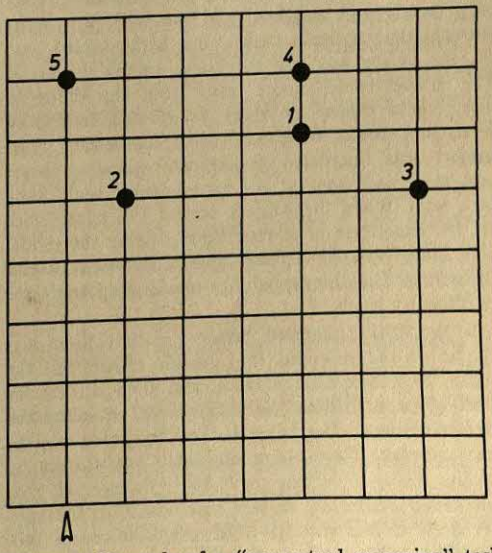

Figure 2. Example of a "perceptual reasoning" task.

cation of the rules. Characteristics of the task were discussed to avoid sudden changes in solution time due to learning. To further reduce the effects of learning on the probability levels to be established, subjects were presented with 10 tasks from each difficulty level and urged to work at tasks from each level until they felt that performance at that level had stabilized and improvement was no longer forthcoming. In addition, the experimenter timed the subjects and was able to verify the stabilization of solution times at each level when the solution times for three consecutive trials varied no more than $\pm \frac{1}{2}$ sec.

When the performance on all five difficulty levels had stabilized, the experimenter selected for the upcoming probability-establishing trials a time limit that would maximize the chances of inducing probabilities of .8, .6, .5, .3, and .1 for the respective difficulty levels. Six tasks from each of the five difficulty levels were presented, and if necessary, slight adjustments were made in the time limit to produce 5, 4, 3, 2, and 1 successes at the respective difficulty levels. The answers were then checked in front of the subject, and the corresponding probabilities, .83, .67, .50, .33, and .17, were computed. These odd and asymmetric probabilities were chosen to maximize credibility of personal probabilities. Labels with these personal probability values were placed in view next to the stacks of corresponding tasks.

Free-Choice Condition

The next phase of the experiment varied, depending on whether the subject had randomly been assigned to the free-choice situation or the forced-choice situation. In the free-choice condition, 50 tasks from each of the five difficulty levels were placed in front of the subject. The personal probability levels were in view, and the subject was instructed that 50 more tasks were to be solved, but that he or she was free to choose among the tasks. The subject could choose tasks from any difficulty level, could choose as many as wanted from any level, and could switch as often as desired. The subject was instructed to indicate when a choice had been made so that the experimenter could time each trial. When the subject turned the puzzle face up, the experimenter started timing, using the modal time limit (varying among subjects between 10 and 20 sec) used in the probability-establishing trials for all difficulty levels.

If the subject finished before the time limit was up, he or she recorded the answer, transferred the puzzle to a box on the table, and then turned the sheet of paper behind the puzzle over, revealing the correct answer. The subject then indicated on the sheet whether the answer obtained was correct by circling *S* for a success or *F* for a failure. If time was called before an answer was obtained, the subject drew a line through that trial, indicating failure. The subject then deposited the answer key, along with the puzzle, in the box and made the choice for the next trial. At the start of this group of 50 trials, the experimenter turned his or her chair so that it faced away from the subject. This was explained as being necessary to keep the experimeter from being distracted from timekeeping. The purpose was to minimize social-desirability factors by making it clear to the subject that the experimenter could not know which difficulty level had been chosen. Only after the subject had left the room did the experimenter learn which choices had been made, by examining the sequence of puzzles that had been deposited in the box.

Forced-Choice Condition

In the forced-choice situation, the subject was told that 50 more trials were to be completed in 10 groups of five tasks, one from each difficulty level. Subjects were shown tables of random permutations and told that the order of the difficulty levels in each group of 5 trials would be random. Again, the experimenter turned his or her chair to face away from the subject. The subject worked the puzzles with the modal time limit established in the probability-establishing trials, checking the answers with the keys behind the puzzles in the same way as the free-choice subjects did. At the end of 5 trials, the subject was asked to indicate on the answer sheet which level of task—easy, moderately easy, intermediate, moderately difficult, or difficult—would be chosen if a free choice were allowed. It was emphasized that this choice would not be acted upon. Each subject in the forced-choice situation made 10 of these choices.

The Questionnaire

At the end of the last 50 trials, subjects in both the free-choice and forced-choice conditions were given the questionnaire that had been mentioned earlier. The main purpose of most questions was to maintain the credibility of the earlier statement about the purpose of the experiment. The questions referred to standard setting, expended effort, and expectation of success. The question regarding the predicted number of successes given 10 more trials at each difficulty level is particularly pertinent to this study, since it was used to select those subjects for whom the manipulation of situational factors (time limit, success and failure feedback, etc.) was successful in inducing and maintaining the personal probabilities established with the subject in the early portion of the experiment. If the average of the probabilities reported by the subject on the questionnaire was more than .1 higher or lower than the average of the established probabilities (.50), the subject was excluded from further analysis. On the basis of this criterion, 25% of the subjects were excluded, 4 because of too low and 12 because of too high subjective probabilities.

Treatment of the Data

Only after the individual sessions had been completed were the TAT protocols scored for n Ach by the second author, who had acquired a reliability correlation of .88 with expert-scored testing materials (Atkinson, 1958). The use of code numbers on the TAT protocols and TAQs further decreased the possibility of experimenter knowledge of subject classification during individual sessions. The TAQ was scored as described by Mandler and Cowen (1958) except that 5 intervals instead of 10 were used. The rank order correlation between TAT and TAQ scores was $-.09$ ($n = 64$), a nonsignificant relationship. Because there was a significant difference between the male and female scores on the TAQ, $F(1, 60) = 9.53$, $p < .01$, data were analyzed separately for males and females. Within each sex, subjects were ranked on both measures, with the lowest score given a rank of 1, and so on. Differences between ranks were obtained by algebraically subtracting the subject's rank on the TAQ from his or her rank on n Ach. Those for whom this calculation produced a high positive number were relatively higher on n Ach than on test anxiety and were considered more nearly $M_S > M_F$ individuals. Subjects with resulting high negative rank differences were relatively higher on test anxiety than on n Ach and were considered more nearly $M_F > M_S$ individuals.

Results

Stability of P_s

To check the assumption of stabilized subjective probability of success during the main phase of the experiment, the mean P_s values were computed from P_s reported at the end of the experiment for each difficulty level. The P_s values were computed for each group of subjects and averaged across the five difficulty levels. As shown in Table 1, the average P_s values are very close to the average subjective probabilities ($P_s = .50$) induced at the five difficulty levels prior to the main phase. A three-way analysis of variance did not show any significant differences in mean P_s between groups. These findings were confirmed by separate analyses of the five difficulty levels using the Newman-Keuls algorithm: None of the tests performed indicated a significant increase in subjective probability over the respective induced value.

P_s Preferences

Since frequency of response is commonly considered an index of motivational preference (e.g., Atkinson & Birch, 1970), the mode of P_s values associated with the preferred difficulty levels was determined for each successive block of five trials from the free-choice situation, and the slope and intercept of the regression line describing P_s preference as a function of time (trials) was computed. This was done for each person within each of the four groups in the free-choice situation. A four-way analysis of variance (Sex × Choice × Motive × Blocks) performed on preferred P_s values revealed a significant main effect of the trial blocks, $F(9, 360) = 4.6$, $p < .0001$, and a significant interaction between choice conditions and trial effect. A trend analysis performed separately for the free-choice and the forced-choice group revealed a highly significant linear trend in the free-choice group, $F(1, 207) = 36.7$, $p < 10^{-7}$, and a significant linear trend in the forced-choice group, $F(1, 207) = 5.1$, $p < .05$. Both trends indicate the expected shift to increasingly more difficult tasks during the course of the experiment. No other trends were significant.

Figure 3 shows the mean preferred P_s levels for the 10 sets of five trials for success- and failure-oriented males. The mean slope of the regression line describing the linear trend to more difficult choices was $M = .43$ in the success-oriented male group and $M = .27$ in the failure-oriented male group (cf. Table 2). The two coefficients depart

Table 1
Mean Probability of Success Reported at the End of the Experiment

Group	Free choice		Forced choice	
	M	*SD*	*M*	*SD*
Males				
$M_S > M_F$	.50	.06	.39[a]	.04
$M_F > M_S$	.46	.04	.52	.06
Females				
$M_S > M_F$	.51	.10	.51	.11
$M_F > M_S$	.52	.06	.50	.13

Note. M_S = motive to succeed; M_F = motive to avoid failure.
[a] Departs significantly (.05 level) from induced average probability of success ($P_s = .50$).

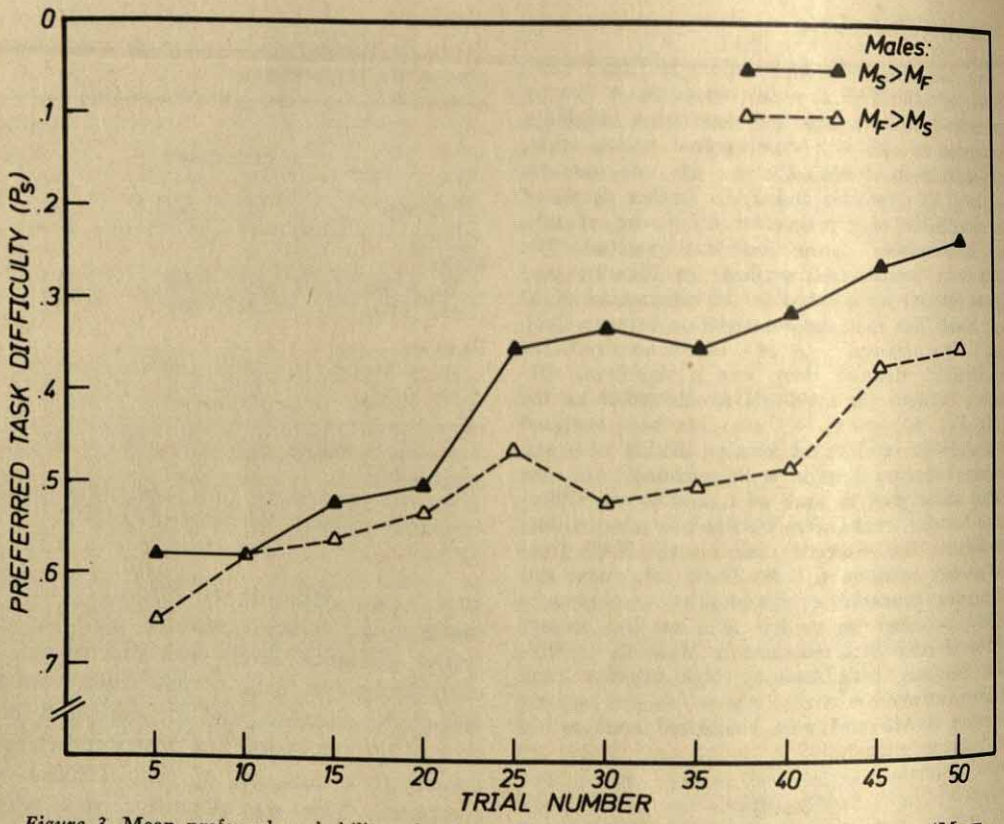

Figure 3. Mean preferred probability of success (P_s) level as a function of motive type (M_S = motive to succeed; M_F = motive to avoid failure) and trials (free choice, males).

significantly from zero, as was expected by Hypotheses 1 and 3; $t(5) = 3.46$, $p < .01$, for success-oriented males, and $t(5) = 4.80$, $p < .0025$, for failure-oriented males. Similar results were obtained for female subjects (cf. Figure 4). The mean slope of the regression line is $M = .26$ for success-oriented females and $M = .22$ for failure-oriented females. The first value approaches statistical significance, $t(5) = 1.55$, $p < .09$, whereas the second value is significantly above zero, $t(5) = 2.59$, $p < .025$. The differences in mean slopes between male and female groups are not significant; $t(10) = 1.24$, *ns*, for success-oriented subjects, and $t(10) = .99$, *ns*, for failure-oriented subjects. The mean slopes from pooled male and female groups are $M = .32$ for success-oriented subjects, and $M = .31$ for failure-oriented subjects. Both values depart significantly from zero; $t(11) = 3.51$, $p < .0025$, and $t(11) = 4.43$, $p < .0005$, respectively.

Table 2
Mean Slopes of Regression Lines for Eight Subject Groups

Group	Free choice		Forced choice	
	Male	Female	Male	Female
$M_S > M_F$	.43[a]	.26	−.03	.23
$M_F > M_S$	.27[a]	.22[a]	.06	.01

Note. $n = 6$ in each cell. M_S = motive to succeed; M_F = motive to avoid failure.
[a] Significantly above zero (.05 level).

The variance of the probabilities preferred by failure-oriented subjects on the first trial of the main phase does not differ significantly from the respective variance for success-oriented subjects, as would be expected if there were any ambivalence between low and high difficulty in failure-oriented subjects, $F(5, 5) = 3.02$, *ns*.

The hypotheses regarding preferred difficulty level at the beginning of the main phase of the experiment (Hypotheses 2 and 4) were confirmed. As can be seen from Table 3, the mean intercepts of the regression line are .63 and .59 for success-oriented males and females, respectively. These values do not differ significantly from the expected value ($P_s = .5$); $t(5) = 2.37$, *ns*, for males, and $t(5) = 1.02$, *ns*, for females. For failure-oriented subjects, the mean intercepts are .65 for males and .71 for females. These values are, as expected (Hypothesis 4), significantly above the intermediate P_s level; $t(5) = 3.37$, $p < .01$, for males, and $t(5) = 3.18$, $p < .05$, for females. Similar results were obtained when first-trial data rather than intercepts were analyzed: The mean P_s level chosen at the first trial was .57 for success-oriented subjects, which does not differ significantly from the expected value (.5); $t(11) = 1.7$, *ns*. For failure-oriented subjects, the mean P_s level chosen at the first trial was .66. This value is, as expected (Hypothesis 4), significantly higher than the intermediate P_s level; $t(11) = 4.17$, $p < .001$. The difference in mean P_s level between motive types approaches significance, $t(22) = 1.53$, $p < .07$ (cf. Hypotheses 3 and 4).

Table 3
Mean Intercepts of Regression Lines for Eight Subject Groups

Group	Free choice		Forced choice	
	Male	Female	Male	Female
$M_S > M_F$	.59	.63	.44	.61
$M_F > M_S$	.65[a]	.71[a]	.49	.57

Note. $n = 6$ in each cell. M_S = motive to succeed; M_F = motive to avoid failure.
[a] Significantly different from probability of success (P_s) = .50.

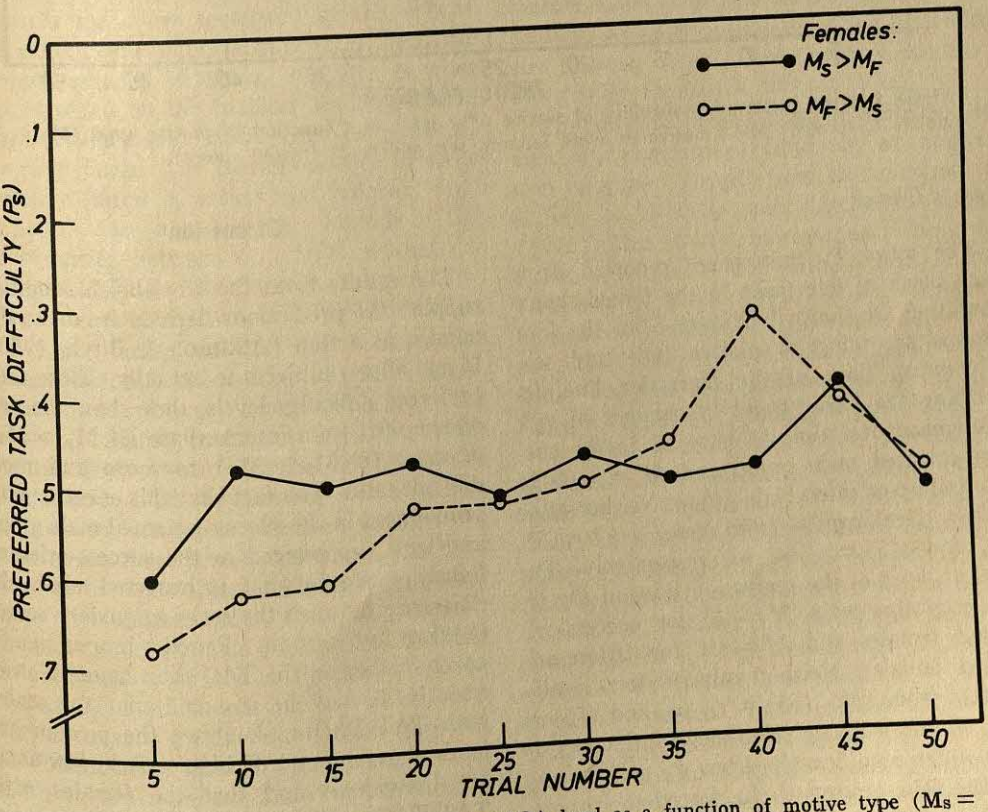

Figure 4. Mean preferred probability of success (P_s) level as a function of motive type (M_S = motive to succeed; M_F = motive to avoid failure) and trials (free choice, females).

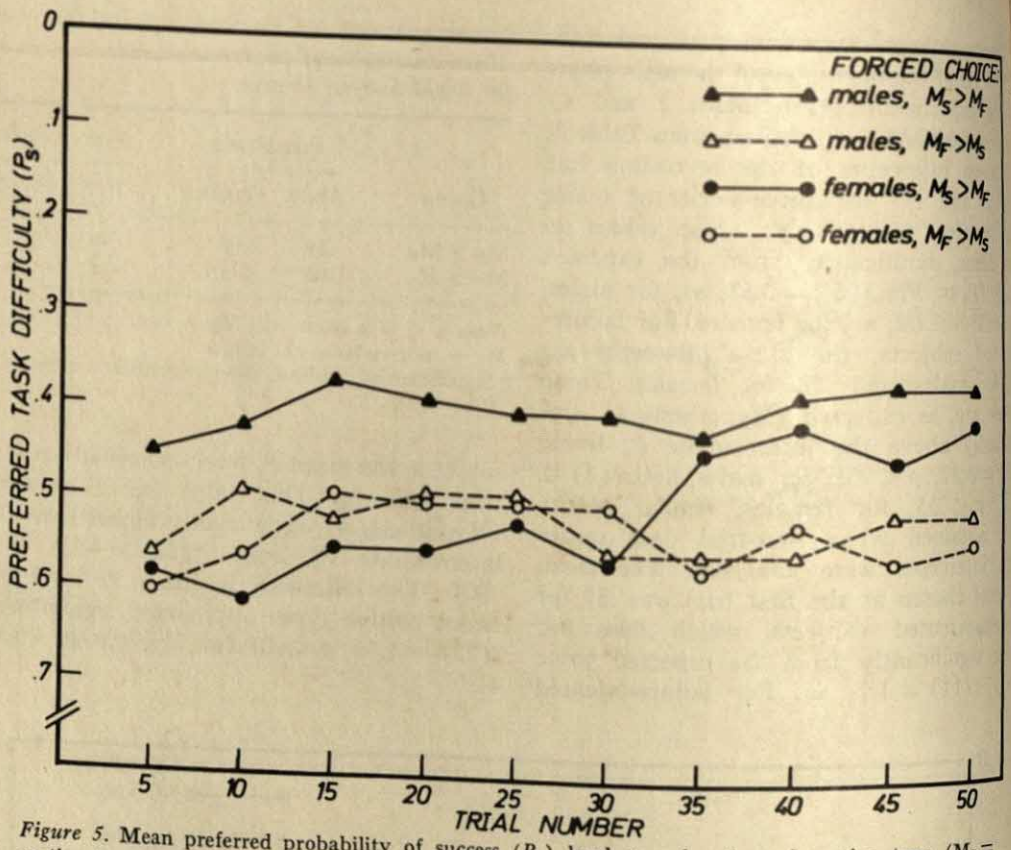

Figure 5. Mean preferred probability of success (P_s) level as a function of motive type (M_S = motive to succeed; M_F = motive to avoid failure), sex, and trials (forced choice).

Forced Choice

The mean P_s preferences reported after each block of five tasks in the forced-choice condition are shown in Figure 5 for the four groups according to motive type and sex. The mean slope of the regression line describing the linear trend in changes of risk preference over time is $M = .03$ in the success-oriented male group and $M = -.06$ in the failure-oriented male group. Neither value differs significantly from zero, $t(5) = .57$, *ns*, and $t(5) = -.64$, *ns*, respectively. The mean slopes of the regression lines in the female groups were $M = .23$ for success-oriented females and $M = .01$ for failure-oriented females. Neither value differs significantly from zero, $t(5) = .6$, *ns*, and $t(5) = .21$, *ns*, respectively. The mean intercepts do not differ significantly from $P_s = .5$ in any of the four groups of the forced-choice condition (cf. Table 3).

Discussion

The results from the free-choice condition support the predictions derived from the dynamics of action (Atkinson & Birch, 1970). If one allows subjects to actually choose their preferred difficulty levels, they show the predicted shift from intermediate (if $M_S > M_F$) or easy (if $M_F > M_S$) to more and more difficult tasks. The fact that this effect is most pronounced in the success-oriented male group and least pronounced in the success-oriented female group is what is expected when the difference between the sexes in anxiety scores is taken into account: Females scored significantly higher on the TAQ than males. Consequently, it may be assumed that the males with TAT-TAQ rank above the median are more characteristic of high n Ach, low-anxiety individuals and that the females with TAT-TAQ rank below the median are more characteristic of low n Ach, high-anxiety indi-

viduals. Females with TAT-TAQ rank above the median may be assumed to have low motivation ($M_S \approx M_F$), since their positive motivation may be dampened by negative motivation, which is significantly greater for females than for males. According to this argument, the insignificant trend obtained by success-oriented females is in line with Hypothesis 5.

The results suggest that there are factors influencing temporal change in risk preference that cannot be explained by changes in P_S. The important implication of this conclusion is that the shift to harder tasks on repeated trials cannot be explained by traditional episodic theories of achievement motivation (Atkinson, 1957; Heckhausen, 1977; Weiner et al., 1971), because subjective probability of success (P_s) was held constant throughout the main phase of the experiment. This is suggested by average P_s judgments obtained at the end of the experiment (Table 1). In the free-choice condition, none of the reported P_s values measured at the end of the experiment differs significantly from the average induced value of .50. This is what was expected on the basis of the assumption that P_s values were stable over trials during the main phase. The correspondence between *objective* initial p_s values and reported final P_s values does not, however, exclude initial discrepancies between objective and subjective probabilities, nor does it exclude increments of latent (not reported) probabilities.

We are facing an old and fundamental methodological problem here: Repeated measurements of subjects' reports do not solve the problem, because they may constitute reactive conditions destroying the validity of the conclusions. The application of objective methods for assessing variables requires, in most cases, more knowledge about the relationship between objective indexes and their subjective determinants than we actually have. Accordingly, our method of checking the assumption of stable P_s values can be viewed as a preliminary compromise only. Yet, the results (Table 1) do show that one possible attempt to falsify the assumption of stable P_s values failed. The conclusiveness of future studies attempting to check hypotheses like ours may be increased if we succeed in developing objective (rather than self-report) techniques of assessing subjective probabilities. A measure of decision time has already yielded some promising results in this direction (Schneider, 1973).

In spite of the encouraging results discussed so far, the validity and generality of the conclusions still have to be investigated in further studies. Results obtained from similar experiments with different tasks and different types of subjects are consistent, though, with the present data in suggesting that there are reasons for the tendency to choose increasingly more difficult tasks that cannot be explained on the basis of respective shifts in expectancy of success alone (Schneider & Posse, 1978; Kuhl, Note 2). These studies also demonstrate that the obtained results cannot be explained by effects due to the spatial arrangement or order of presentation of the various difficulty levels. The explanation offered by the dynamics of action is based on the assumption of greater consummatory value of success than of failure, which leads to relatively quick reduction of tendencies to work on easy tasks because success is more likely than with difficult tasks.

The shift to harder tasks in spite of constant P_s was also predicted by an application of some concepts from the dynamics of action by Revelle and Michaels's theory (1976). This theory, however, sacrifices some of the predictive power of the original theory (Atkinson & Birch, 1970) by neglecting the motivational effects of success and failure on negaction tendencies in failure-oriented subjects. The fact that failure-oriented subjects show a significant though weaker trend to more difficult tasks contradicts Revelle and Michaels's reverse-strategy hypothesis for this motive type. In addition, the limited dynamic theory includes the assumption of constantly active consummation of all competing tendencies, no matter whether a tendency is expressed in behavior. This simplifying assumption has the implication that the theory can only be tested in a situation in which constantly present consummation of all tendencies is approximated by forcing the subjects to work on consecutive series consisting of tasks of all difficulty levels (Revelle, Note 3). The significant interaction between choice

condition and trial effect (compare Figures 2 and 3 with Figure 4) stresses the predictive power of the original theory, which predicted the differential effects in both the free-choice and the forced-choice conditions. The generality of the simplified dynamic theory is limited to the forced-choice situation. The main focus of the dynamics of action, however, is directed towards the "ecologically more representative" (Brunswick, 1952) situations allowing free expression of preferred tendencies over extended periods of time.

A final word may be said about a *phenomenological* interpretation of the results. The shift to more difficult tasks in spite of constant P_s may be described in terms of a "cognitive strategy" involving a shift to a higher difficulty level after one or more successes on a given difficulty level have been experienced. Cognitive interpretations of behavioral data have been contrasted to "mechanistic" explanations (i.e., explanations that do not describe cognitive mediators explicitly; Weiner, 1972). According to our view regarding this controversy, the difference between a phenomenological and a *functional* explanation, as we prefer to call the one offered in this article, is not a difference between contradicting theoretical positions, but a difference between two epistemological perspectives on the same phenomenon. Accordingly, we believe that the functional explanation offered by the dynamics of action in terms of differential consummatory values after success and failure is compatible with a phenomenological explanation describing the cognitive processes that may be coordinated to the functional parameters discussed here.

Effects of Paced Respiration and Expectations on Physiological and Psychological Responses to Threat

Kevin D. McCaul, Sheldon Solomon, and David S. Holmes
University of Kansas

While waiting to receive electric shocks, 105 males either (a) regulated their breathing at one half the normal rate, (b) regulated their breathing at the normal rate, or (c) did not regulate their breathing rate. Half of the subjects in each breathing condition were told that their breathing task would aid them in relaxing, whereas the other half were not given that expectation. Subjects in a no-threat condition were not threatened with shocks, did not regulate their breathing, and were not provided with expectations. The results indicated that slowing respiration rate reduced physiological arousal as measured by skin resistance and finger pulse volume (but not heart rate) and reduced self-reports of anxiety. Expectations did not influence arousal. These data provide evidence for the effectiveness of paced respiration as a coping strategy, and they resolve the conflicting findings of previous investigations.

Considerable attention is being devoted to determining the effectiveness of various strategies for controlling the physiological arousal and anxiety experienced during threatening situations. One such strategy involves the control of respiration. Controlling respiration may be effective for reducing physiological arousal because there are strong general relationships among the various physiological response systems (cf. Davies & Neilson, 1967; Levenson, 1976; Obrist, Webb, & Sutterer, 1969; Stroufe, 1971). Control over respiration may also be effective for reducing anxiety, because if it does reduce physiological arousal, there would be fewer cues to stimulate self-reported anxiety (Schachter, 1964).

Surprisingly, only two experiments have been conducted specifically to test the effects of controlled respiration on persons' responses to threat. In the first investigation (Harris, Katkin, Lick, & Habberfield, 1976), subjects participated in either (a) a *paced-respiration* condition in which they were instructed to synchronize their respiration to a light that came on and went off at a rate of 8 cycles per minute, a rate half that of the normal resting respiration rate; (b) an *attention* control condition in which they simply counted the light cycles and signaled the experimenter after every 10 cycles; or (c) a *baseline* control condition in which they were not given any instructions concerning the flashing light. All subjects were then presented with two tones that they were told might be followed by electrical shocks (the first one was). The investigators reported that when the first tone was presented, subjects in the paced-respiration condition evidenced smaller electrodermal responses (though not smaller heart rate responses) than did subjects in the other two conditions. Regrettably, these results must be interpreted with caution, because the investigation suffered from a number of methodological and statistical problems (see Holmes, McCaul, & Solomon, 1978).

In the second investigation (Holmes et al., 1978) subjects were first asked to rest for a

This research was supported by biomedical research and general research fund grants from the University of Kansas to David S. Holmes. The authors would like to thank Rusty Brown and B. Kent Houston for their assistance with the project.

30-min. period during which their respiratory patterns were recorded. Subjects then participated in either (a) a *respiration-tracing* condition in which they were shown a record of their resting respiratory patterns and were instructed to breathe in such a way that the pen tracing their present respiratory pattern traced the line representing their resting respiratory pattern—a procedure that required subjects to duplicate in all respects (rate, depth, and phasing of rate and depth) their resting respiratory activity; (b) an *attention-tracing* control condition in which they were shown a record of their resting respiratory patterns and were instructed to manipulate a knob in such a way that a pen connected to the knob traced the line representing their resting respiratory pattern; or (c) a *no-tracing* control condition in which they were not shown a record of their resting respiratory pattern and simply sat quietly. Once the respiration manipulation was completed, half of the subjects in each condition were threatened with electrical shocks, whereas the other half were not. Contrary to what was expected, analyses of heart rate and self-report data indicated that the respiration manipulation was not effective for decreasing arousal. (Unfortunately, apparently because of technical problems with the equipment, in this experiment the skin resistance measure was insensitive to changes in arousal and thus could not be used for testing the hypothesis.) In contrast to the first experiment, then, the second experiment offered no evidence for the effectiveness of controlled respiration for reducing arousal under threatening conditions.

Apart from their results, the two experiments described above differed in a number of important respects; for example, (a) one experiment employed a respiration rate that was one half the normal resting rate, whereas the other employed the normal resting rate; (b) respiration was controlled with different techniques; and (c) one experiment found the predicted effects only with the skin resistance measure, whereas that measure was not available in the other. Because of these differences, it did not seem possible to resolve the conflict in the results of the two experiments, and thus it was not possible to draw a firm conclusion concerning the effectiveness of controlled respiration for reducing arousal under threatening conditions.

The present experiment was conducted in an attempt to resolve the conflicts between the two previous experiments. Because it was felt that *slowed* respiration might be the crucial difference between the earlier experiments, in the present experiment subjects were threatened with painful electrical shocks while (a) their respiration rates were regulated at one half of the normal resting rate (*slow-breathing* condition); (b) their respiration rates were regulated at the normal resting rate (*normal-breathing* condition); or (c) their respiration rates were not regulated (*nonregulated-breathing* condition). It was predicted that subjects who had their breathing regulated at a slow rate would evidence less physiological arousal and report less anxiety than subjects who had their breathing regulated at a normal rate or subjects who did not have their breathing regulated. In addition, it was expected that breathing at a normal rate would not reduce arousal or anxiety relative to breathing at a nonregulated rate.

Although respiration *rate* appears to represent the chief difference between Harris et al. (1976) and Holmes et al. (1978), it is conceivable that the respiration manipulations used in those experiments also influenced subjects' respiration *depth*. Unfortunately, data concerning respiration depth were not reported in either of those earlier studies. This issue is important because of the results of several studies that have examined the influence of paced respiration in nonthreatening situations. In one of those studies it was concluded that respiration rate per se influenced heart rate (Levenson, 1976), but other investigations suggested either that rate has no effects (Engel & Chism, 1967; Epstein & Webster, 1975) or that it is the combination of changes in rate and depth that influences measures of arousal (Deane, 1965; Stroufe, 1971). Thus, even though the experimental manipulation employed in the present investigation was focused on respiration rate, both rate and depth were monitored.

In addition to examining respiration control, this experiment also investigated the possible effects of the expectations subjects hold about the coping strategy of respiration control. Because expectations concerning the effects of the breathing manipulations might have an influence on arousal (i.e., a placebo-like effect), half of the subjects were given explicit expectations that what they were doing would aid them in reducing arousal (*high-expectations* condition), whereas the other half were not given those expectations (*no-expectations* condition).

So that the influence of the threat, respiration, and expectation manipulations could be assessed relative to a nonthreatened group whose respiration was not regulated, a control condition was employed in which subjects were not threatened, breathing was not regulated, and expectations were not provided (*no-threat* control condition).

Method

Design

This experiment employed a 3 (slow breathing, normal breathing, nonregulated breathing) × 2 (high expectations, no expectations) factorial design in which all subjects were exposed to a threat, plus a one-cell control condition (nonregulated breathing, no expectations) in which subjects were not exposed to a threat.

Subjects and Laboratory Facilities

One hundred and ten male undergraduates at the University of Kansas participated individually in the experiment as part of their research requirement for a general psychology course.[1] The subjects were assigned randomly to the seven conditions formed by the 3 × 2 + 1 design. One subject's data were discarded because he did not understand the procedures, and 4 of the 93 subjects assigned to the threat conditions elected not to continue in the experiment. Therefore, the results are based on 105 subjects and cell *n*s range from 14 to 16.

While participating in the experiment, the subject sat at a desk in a straight-backed chair in a sound-attenuated room. A video monitor with a 30-cm screen (measured diagonally) was mounted at eye level 90 cm in front of the subject. The screen was vertically divided in half by a red stripe 2 cm wide. A control room that directly adjoined the experimental room contained a Beckman polygraph, a Sony video system, and a tape recorder that were used to record physiological responses, present visual materials, and present the instructions.

Procedure

Upon arrival, the subject was told that the experiment involved studying physiological responses to various types of stimulation. After the subject agreed to participate by signing an informed-consent statement, he was seated, and the physiological sensors were attached. Specifically, a Beckman photoelectric plethysmographic finger transducer was attached to the middle finger of the subject's nondominant hand; 20 × 25 mm monopolar Lafayette chrome skin resistance electrodes were attached to the second and fourth fingers of the same hand; and a Beckman strain gauge was placed around the subject's chest.[2] In addition, a large electrode was strapped to the subject's left wrist. That electrode was later described as a shock electrode to the subjects in the threat conditions.

The subject was then asked to sit quietly and relax for 5 min. After 5 min., the subject was instructed to complete an 18-item anxiety checklist that used adjectives taken from the Affect Adjective Checklist (Zuckerman, 1960). For each adjective, the subject checked a 4-point scale (1 = "not at all"; 4 = "a great deal") that reflected the degree to which that adjective described how he felt at that time. Responses to this checklist were used as a measure of the subject's initial level of anxiety.

Threat manipulation. After the subject completed the anxiety checklist, the experimenter reentered the room and gave the subject a second informed-consent statement. The form given to subjects in the threat conditions indicated that the stimulation being studied was "painful electric shock" and then asked the subject to rate on a 61-point scale (1 = "not at all"; 61 = "extremely") how concerned he was about receiving shocks. After the subject agreed to continue participating and indicated his concern about receiving shocks, the experimenter left the room and started the audiotape that described the shock procedure. The description indicated that after the instructions were completed, a green signal light would come on, indicating the beginning of a 90-sec "waiting (anticipation) period" to be followed by the onset of a red signal light indicating the beginning of a 90-sec "shock (threat) period," during which up to three shocks would be administered on a random schedule through the electrode on the subject's left wrist.

---

[1] Male subjects were used because of their availability in the subject pool. It might be noted that in the previous, similar experiment (Holmes et al., 1978), no differences between males and females were found on either physiological or self-report measures. Therefore, there was little reason to expect differences in this experiment.

[2] Skin resistance was recorded using constant voltage (see Venables & Christie, 1973).

In contrast, the second informed-consent statement given to each subject in the no-threat condition indicated that the stimulation being studied was "visual stimulation." After the subject agreed to continue participating, the experimenter left the room and started an audiotape that described the procedure for receiving the visual stimulation. The description indicated that after the instructions were completed, a green signal light would come on, indicating the beginning of a 90-sec "waiting period" to be followed by the onset of a red signal light that would provide 90 sec of visual stimulation.

Breathing manipulation. After receiving the instructions for the shock or visual stimulation, the subject was directed to look at the video monitor mounted in front of him. In the slow-breathing and normal-breathing conditions, a Sony video recorder was used to project a sine curve that moved from right to left across the monitor. The subject was instructed to watch the curving line as it passed the red line that divided the screen and to breathe so that he inhaled as the line went up and exhaled as the line went down. In addition, the subject was admonished not to hold his breath or to take huge breaths, but to breathe slowly and smoothly throughout each curve.

In the slow-breathing condition, the videotape was recorded to regulate the subject's respiration at a rate of approximately 8 breaths per minute. This is one half the normal rate, and it is the rate that previous investigators have employed in studying the effects of slowed breathing on arousal (see Harris et al., 1976). In the normal-breathing condition, the videotape was recorded to regulate the subject's respiration at a rate of approximately 16 breaths per minute. This rate was selected because previous research indicated that this was the rate at which subjects in similar experiments breathed when not under stress (see Harris et al., 1976; Holmes et al., 1978). Each subject in the nonregulated-breathing conditions was simply instructed to watch a test pattern on the video monitor. In all conditions, the subject was instructed to continue the task assigned to him until the end of the experiment.

Expectation manipulation. Half of the subjects in the threat condition were assigned to the high-expectations condition. After practicing the breathing task or watching the test pattern for approximately 2 min., they were told that their task was effective for reducing stress; that is, the subject was told either that regulated breathing or attending to a video monitor was an exercise designed to help people relax and stay calm. Furthermore, each of these subjects was informed that the exercise had been found to be effective for reducing stress in many previous experiments.

The other half of the subjects in the threat condition, as well as subjects in the no-threat condition, were assigned to the no-expectations condition. They were told either that regulating breathing or that attending to the video monitor was desirable in experiments using physiological measures because it kept their breathing or attention constant while allowing other physiological indexes like heart rate and skin resistance to vary. They were thus given no particular expectation that the tasks would be useful for reducing stress. After the expectation manipulation was completed, each subject in the threat condition was briefly interrupted and asked to report on a single-item questionnaire how relaxed he expected to be during the shock period. Responses to this item served as a check on the expectation manipulation.

When those procedures were completed, each subject was reminded to continue performing his specific task during the wait and during the shock/stimulation periods. The lights then came on as announced, but no shocks were actually administered. Following the 90-sec shock/stimulation period, each subject was asked to complete another anxiety checklist describing how he felt during the shock/stimulation period. Each subject in the threat condition was also asked to describe his thoughts and feelings while waiting for the shock and to report what he thought about to keep calm during the shock period. The session then concluded, and the subject was completely debriefed concerning the procedures, deception, and purpose of the experiment.

Results and Discussion

Scoring and Preparation of Physiological Data

The skin resistance data were scored for seven 30-sec periods: The highest level of resistance (lowest arousal) was determined for the last 30-sec period of the baseline period that preceded any of the experimental manipulations, and the lowest level of resistance (highest level of arousal) was determined for each of the three 30-sec periods in the anticipation period and each of the 30-sec periods in the threat period (or "visual stimulation" period, in the case of subjects in the no-threat condition).[3] To eliminate the influence of initial levels of arousal on subsequent levels of arousal (i.e., the "law of initial values"; Lacey, 1956; Wilder, 1962), the scores from the anticipation and threat periods were residualized (Cronbach & Furby, 1970) using the scores from the baseline period as the measures of initial levels of

[3] The highest skin resistance level (lowest arousal) was chosen as the best initial measure of skin resistance, to avoid taking into account brief fluctuations in the final 30 sec of the baseline procedure. This procedure appears to have been effective, since the average pretest–posttest correlation for skin resistance level was greater than .90.

arousal. (A residualized score consists of the difference between the score obtained during a given period and the score predicted by linear regression from the baseline score.) The scores for the periods within the anticipation period were averaged to obtain one score for the anticipation period, and the same was done for the threat period.[4]

Heart rate and finger pulse volume were scored for the same seven 30-sec periods. Heart rate was defined as the number of beats occurring in the period. Finger pulse volume (in mm) was determined by averaging the largest volume (lowest arousal) and the smallest volume (highest arousal) during each period. Both the heart rate and finger pulse volume scores were then residualized and averaged like the skin resistance scores.

Respiration rate was scored for seven 30-sec periods: the 30-sec period after the breathing manipulation, the three 30-sec periods during the anticipation period, and the three 30-sec periods within the threat period. The scores within the anticipation and threat periods were then averaged. Respiration rate was simply defined as the total number of breaths taken during the 30 sec. Respiration depth, measured (in mm) from the bottom to the top of an inspiration, was scored for the breath approximately in the middle of each of the same seven periods, as well as the baseline period. These scores were then adjusted and averaged like the skin resistance scores.

Effectiveness of Experimental Manipulations

Threat manipulation. Comparisons of the skin resistance scores of the subjects in the six threat conditions with the skin resistance scores of the subjects in the no-threat condition revealed that across the anticipation and threat periods, subjects in the threat conditions showed lower resistance (higher arousal) than subjects in the no-threat condition, $F(1, 92) = 7.07$, $MS_e = 8057.73$, $p < .01$.[5] Comparable comparisons conducted on the heart rate data revealed that across periods, subjects in the threat conditions evidenced higher heart rates than subjects in the no-threat condition, $F(1, 97) = 6.38$, $MS_e = 18.28$, $p = .01$. Analyses of the finger pulse volume data showed similar results, $F(1, 97) = 47.25$, $MS_e = 22.40$, $p < .01$. Finally, it was found that subjects in the six threat conditions reported significantly higher anxiety than did subjects in the no-threat condition, $F(1, 96) = 20.89$, $MS_e = 68.00$, $p < .01$. These results consistently indicate that the threat manipulation was effective in increasing subjects' physiological arousal and reported anxiety.

Respiration manipulation. A 3 (respiration) × 2 (expectations) × 3 (periods) analysis of variance with repeated measures conducted on the respiration rate scores revealed that only the respiration effect was statistically significant, $F(2, 80) = 114.71$, $MS_e = 3.46$, $p < .01$. Subsequent comparisons indicated that subjects in the slow-breathing condition showed a slower respiration rate than subjects in either the normal-breathing or nonregulated-breathing conditions, $ts(120) = 9.92$ and 10.83, respectively, $ps < .01$. There was no difference in respiration rate between the latter conditions ($Ms = 4.31$, 7.75, and 8.17, respectively).

A 3 (respiration) × 2 (expectations) × 3 (periods) analysis of variance with repeated measures conducted on the respiration depth scores revealed that only the respiration effect was statistically significant, $F(2, 82) = 11.02$, $MS_e = 204.73$, $p < .01$. Subsequent comparisons (Duncan's) indicated that subjects in the slow-breathing condition breathed more

---

[4] Initial analyses indicated that there were no pretest differences among conditions on any of the measures used as covariates. Other analyses indicated that the consideration of 30-sec periods within the anticipation and stress periods contributed no new information; therefore, for both heart rate and skin resistance, the factor representing 30-sec periods was eliminated to make the analyses less complex and to reduce the possibility of chance findings.

[5] Degrees of freedom for the analyses to be presented differ slightly for two reasons. First, six subjects were missing skin resistance scores, and one subject was missing heart rate and finger pulse volume scores. Second, in analyzing the self-report measures, a covariate (initial fear of shock) was used that was not gathered for no-threat subjects. Thus, the overall error term derived from all subjects could not be used for self-report measures. Comparisons between experimental and control subjects on the anxiety checklist were performed using only one covariate: initial anxiety checklist scores.

deeply than subjects in the other respiration conditions ($ps < .05$). Respiration depth for subjects in the normal and nonregulated respiration conditions did not differ ($Ms = 25.63$, 19.94, and 16.39, respectively).

The findings concerning respiration indicate that the respiration manipulation was effective for slowing subjects' respiration rate. At the same time, however, the manipulation affected respiration depth; subjects who were induced to breathe slowly took deeper breaths. Furthermore, since none of the other effects generated by these analyses was statistically significant, it appears that respiration was not influenced by the other manipulations and that subjects maintained their respiration rate and depth over time.

Expectations manipulation. A 3 (respiration) × 2 (expectations) analysis of covariance was conducted on the scores indicating how relaxed subjects expected to be during the threat period; subjects' initial levels on the fear of shock and the anxiety checklist measures were used as covariates. This analysis revealed that only the expectations effect was statistically significant, $F(1, 81) = 5.29$, $MS_e = 99.27$, $p = .02$. Inspection of the adjusted means indicated that subjects in the high-expectations condition reported expecting to be more relaxed than subjects in the no-expectations condition ($Ms = 29.31$ and 24.33, respectively). The fact that none of the other effects generated by the analysis was statistically significant indicates that subjects' expectations were not influenced by the respiration manipulation.

Summary. The results clearly indicate that (a) the threat manipulation was effective for increasing subjects' physiological arousal and reported anxiety, (b) the respiration manipulation was effective for slowing subjects' respiration rate, and (c) the expectation manipulation was effective for increasing the degree to which subjects thought they would be able to relax while waiting for shocks. In view of the effectiveness of the various experimental manipulations, it is appropriate to consider whether slowed respiration and expectations were effective in reducing the arousal and anxiety of subjects undergoing threat.

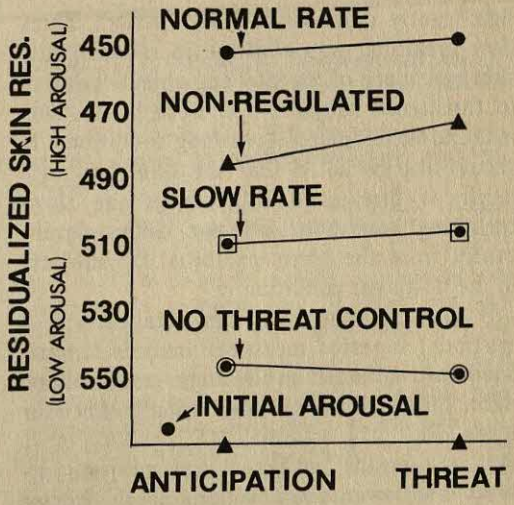

Figure 1. Mean residualized skin resistance scores for the breathing conditions and the no-threat control condition during the anticipation and threat periods. (Cell means are based on the following number of subjects: no-threat control, $n = 14$; slow breathing, $n = 29$; nonregulated breathing, $n = 28$; normal breathing, $n = 28$.)

Effects of Slowed Respiration

Physiological responses. A 3 (slow breathing, normal breathing, nonregulated breathing) × 2 (high expectations, no expectations) × 2 (anticipation period, threat period) analysis of variance with repeated measures conducted on the skin resistance data revealed a respiration effect that closely approached significance, $F(2, 92) = 2.87$, $MS_e = 15827.44$, $p = .06$, and a Respiration × Periods interaction that was statistically significant, $F(2, 92) = 3.48$, $MS_e = 288.02$, $p = .03$. The means contributing to this interaction are presented graphically in Figure 1.

To test the prediction that slowed respiration would be effective for reducing physiological arousal, a contrast was performed comparing the skin resistance level of subjects in the slow-breathing condition to the skin resistance level of subjects in the combined normal and nonregulated conditions. This contrast was significant for both the anticipation period, $F(1, 92) = 3.95$, $MS_e = 8057.73$, $p = .05$, and the threat period, $F(1, 92) = 5.42$, $MS_e = 8057.73$, $p = .02$. The skin resistance levels of subjects in the normal and nonregulated conditions were not

significantly different in either period. Thus, slow breathing was effective in reducing the skin resistance of threatened subjects relative to threatened subjects who were in the normal and nonregulated breathing conditions. It should also be noted that the skin resistance levels of threatened subjects in the slow-breathing condition did not differ significantly from the levels exhibited by subjects in the no-threat condition.

A 3 (respiration) × 2 (expectations) × 2 (periods) repeated measures analysis of variance was conducted on the finger pulse volume data. This analysis revealed a main effect for trials, $F(1, 97) = 8.65$, $MS_e = 3.42$, $p < .01$; the means indicated that subjects exhibited a lower pulse volume level (higher arousal) during the threat than during the anticipation period. The analysis also revealed a significant effect for respiration, $F(2, 97) = 3.30$, $MS_e = 41.39$, $p = .04$.

To test the prediction that slowed respiration would be effective for reducing physiological arousal, a contrast was performed comparing the finger pulse volume level of subjects in the slow-breathing condition to the finger pulse volume level of subjects in the combined normal and nonregulated conditions. Across periods this contrast was significant, $F(1, 97) = 5.43$, $MS_e = 22.40$, $p = .02$. The finger pulse volume levels of subjects in the normal and nonregulated conditions were not significantly different (Ms = 9.22, 6.22, and 7.23, respectively). Thus, slow breathing was effective in reducing the finger pulse volume of threatened subjects relative to threatened subjects who were in the normal and nonregulated breathing conditions. It should be noted, however, that subjects in the slow-breathing condition exhibited more arousal than subjects who were not threatened, $F(1, 97) = 25.81$, $MS_e = 22.40$, $p < .01$.

Analyses conducted on the heart rate data did not reveal any statistically significant main effects or interactions involving respiration.

Self-report responses. A 3 (respiration) × 2 (expectations) analysis of covariance was conducted on the anxiety scores. Subjects' scores on both the self-report measure of initial fear of shock and on the first anxiety checklist were used as covariates. The analysis of covariance revealed only a respiration effect that approached statistical significance, $F(2, 81) = 2.54$, $MS_e = 65.76$, $p = .08$. To test the prediction that slowed respiration would be effective for reducing psychological anxiety, a contrast was performed comparing the self-reported anxiety of subjects in the slow-breathing condition to the anxiety reported by subjects in the combined normal and nonregulated breathing conditions. This contrast was statistically significant, $F(1, 81) = 4.89$, $MS_e = 65.76$, $p = .03$. A comparison of the anxiety reported by subjects in the normal-breathing and nonregulated-breathing conditions was not significant (Ms = .75, 5.37, and 4.26, respectively). These data suggest that slow breathing was a successful technique for reducing psychological stress. It should be noted, however, that subjects in the slow-breathing condition reported more anxiety than did subjects who were not threatened with shock, $F(1, 96) = 10.96$, $MS_e = 68.00$, $p < .01$.

Effects of Expectations

The factorial analyses of variance, described above, that were conducted on the skin resistance, finger pulse volume, heart rate, and self-report data did not reveal any main effects or interactions involving expectations that reached or approached statistical significance. The consistent absence of those effects and the absence of meaningful ordering of means clearly indicates that in this investigation, differential expectations concerning the effectiveness of the coping strategy subjects were employing did not influence the actual effectiveness of the strategies.

Conclusions and Implications

This experiment provides support for the conclusions of Harris et al. (1976) that paced respiration can be effective for reducing arousal under threatening conditions. The data also suggest that the conclusions of Holmes et al. (1978) that controlled respiration is ineffective for reducing arousal must be qualified. Specifically, when respiration was controlled by slowing it to a rate well below normal, as in Harris et al., subjects evidenced

higher skin resistance and higher finger pulse volume levels, and they reported lower levels of subjective anxiety than did subjects in the other conditions. In contrast, when respiration was controlled at a normal, resting rate, as in Holmes et al., no beneficial effects for controlled respiration were found. The similarity of these results across both physiological and self-report measures provides converging validity for the effects of the slow-breathing strategy.

Despite the strength of these results, it is important to recognize two points. First, on both the self-report measure of anxiety and on the finger pulse volume measure, subjects who were threatened and who used slow breathing exhibited greater arousal than non-threatened subjects. Clearly, by itself, the slowed-breathing strategy is not a panacea for problems of arousal.

Second, the data concerning respiration demonstrated that subjects who were induced to change their respiration rate also changed their respiration depth; thus, it is not clear whether it was the change in rate, depth, or some combination of rate and depth that resulted in the reduction of arousal. From a pragmatic standpoint (e.g., using the slow-breathing strategy to reduce anxiety), it is clear that the manipulation of respiration rate influences arousal, and the question of whether rate or depth or some combination mediates these effects may not be crucial. From a theoretical standpoint, however, this question is important if we are to understand the phenomenon, and it may deserve further attention.

In summary, the present experiment emphasizes the importance of examining physiological strategies for controlling physiological and psychological stress. If social–personality psychologists are going to make a maximal contribution to the process of stress control, their efforts should include physiological components along with the cognitive components they have already studied and found to be effective.

Interpersonal Attraction in Aversive Environments: A Problem for the Classical Conditioning Paradigm?

Douglas T. Kenrick and Gregory A. Johnson
Montana State University

Several studies have found decreased attraction for a stranger rated under aversive conditions, and these studies have been used to support a model that views attraction as a function of generalization of affect. A number of studies, however, have failed to support such a model, not only failing to show decreases in attraction as a function of negative circumstances but often showing the reverse, that is, enhanced attraction under aversive conditions. It is suggested that studies that have supported the affective generalization model may be limited in ecological validity as a function of their use of a "simulated stranger" paradigm and that results from studies in which "real" strangers are rated can be understood within a negative reinforcement model. Original data from a study in which female subjects rated both a fellow subject and a bogus stranger under conditions of either aversive noise or low-level noise are presented to support such a resolution.

Research stimulated by the reinforcement model of attraction (Byrne, 1971; Clore & Byrne, 1974; Lott & Lott, 1974) has produced an abundance of evidence supporting the idea that persons will come to like others associated with positive affect and dislike others associated with negative affect. With regard to the latter phrase of this proposition, a number of studies done to test a classical conditioning model of attraction have in fact shown that arousal of aversive affect leads to decreased interpersonal attraction (Gouaux, 1971; Griffitt, 1970; Griffitt & Veitch, 1971; Veitch & Griffitt, 1976). There is at the same time, however, a large body of seemingly contradictory findings. For instance, anecdotal evidence suggesting that individuals often become highly attracted to one another under aversive circumstances (Byrne, Allgeier, Winslow, & Buckman, 1975; Rubin, 1973, pp. 5–7) is supported by similar correlational findings (Driscoll, Davis, & Lipetz, 1972; Rubin, 1973, pp. 228–230). Likewise, a number of experimental studies of attraction under aversive circumstances (Bell, 1978; Bell & Baron, 1974, 1976; Byrne et al., 1975; Dutton & Aron, 1974; Kenrick, Cialdini, & Linder, 1979; Latané, Eckman, & Joy, 1966; Morris et al., 1976; Brehm, Gatz, Goethals, McCrimmon, & Ward, Note 1) have failed to show a classical conditioning effect and often show the opposite pattern (i.e., aversive circumstances increasing attraction).

Negative Reinforcement or Generalization of Negative Affect?

Although it is possible to interpret the latter findings as inconsistent with reinforcement principles (Berscheid & Walster, 1974), Kenrick and Cialdini (1977) suggested that these data could be parsimoniously explained as consistent with a *negative reinforcement* model. Briefly, since the presence of others has been found to reduce aversive arousal arising from such situations (Back & Bogdonoff, 1964; Bovard, 1959; Conger, Sawrey, & Turrell, 1958; Wrightsman, 1960), subjects in

The authors wish to thank Robert B. Cialdini for his comments on an earlier version of this manuscript. We would also like to express our appreciation to Robert A. Baron, whose help extended well beyond the call of duty of a topic editor.

these experiments would be expected to find another's presence reinforcing, and hence reported attraction would be quite consistent with reinforcement principles. In the Dutton and Aron (1974) study, for instance, there was evidence that the target person did in fact reduce subjects' anxiety levels. According to this formulation, the reinforcement model of attraction is not incorrect at all. In this case, it must simply be kept in mind that positive affect is aroused not only by the onset of a rewarding stimulus (positive reinforcement) but also by the offset of a punishing stimulus (negative reinforcement).[1]

Although such an account is consistent with the reinforcement formulation of attraction (Byrne, 1971; Clore & Byrne, 1974; Lott & Lott, 1974), there remains nevertheless a disturbing inconsistency in the literature, with one group of studies suggesting that we will come to dislike others we meet under aversive circumstances (e.g., Griffitt, 1970; Griffitt & Veitch, 1971) and another group of studies contradicting this suggestion (e.g., Driscoll et al., 1972; Dutton & Aron, 1974). We would thus seem to have a situation in which reinforcement theory has little predictive utility. However, if one compares those studies supporting the *simple* affective generalization model with those which fail to support the model, one very consistent difference emerges. In those studies lending support to such a model, the target person was not physically present. In the remaining studies, on the other hand, which support an expanded negative reinforcement version of the model, the target person was actually present contiguous with the aversive stimuli.

Influence of Aversive Affect on Ratings of a "Bogus Stranger"

In the Griffitt and Veitch (1971) experiment, subjects were exposed to conditions varying from "hot and crowded" to roomy and comfortable. As predicted, ratings of strangers were negatively influenced by both uncomfortable heat and by crowding. The strangers rated, however, were not the other subjects present in the experimental chamber but were simulated strangers (Byrne, 1971). The simulated stranger in the Griffitt & Veitch (1971) experiment was described as a student of the same sex as the subject, who had participated in another study during the previous semester. The subject was shown a copy of an attitude survey ostensibly filled out by this person (in actuality, the attitude ratings were filled out by the experimenter so as to appear to be either similar or dissimilar to the subject's own attitudes). Similarly, subjects in the Griffitt (1970), Gouaux (1971), and Veitch and Griffitt (1976) studies rated such an artificially simulated stranger. Hence, when a target person is not physically present, there is reason to believe that negative affect generated by unpleasant circumstances will generalize to that other, leading to a negative impression.

Aversive Affect and Ratings of Another who is Physically Present

The Dutton and Aron (1974) and Brehm et al. (Note 1) studies, on the other hand, had subjects (who were or were not expecting painful electric shock) rate a physically present confederate who posed as a fellow subject. In these experiments, there was increased attraction for the confederate under the relatively more aversive circumstances. Byrne et al. (1975) likewise found increased attraction for same-sex others under relatively more aversive circumstances and suggested that these results "create potential problems within the larger context of the reinforcement–affect model of attraction" (Byrne et al., 1975, p. 11). Although this study also used a bogus attitude profile, however, as did studies by Bell (1978) and Bell and Baron (1974, 1976), subjects in these studies were led to believe that the profile had been filled out either by a confederate or by another subject who actually participated in the same experiment along with the sub-

[1] This term is often mistakenly interchanged with the term *punishment*. As used by contemporary learning theorists (e.g., Rachlin, 1970), however, negative reinforcement refers to the termination of an aversive stimulus, whereas punishment refers to its onset, which of course has more or less opposite consequences.

ject.[2] Similarly, Latané et al. (1966) reported highest attraction for same-sex others who were *present* under relatively more fear-producing conditions, whereas in correlational studies of the influence of adverse conditions on attraction (Driscoll et al., 1972; Rubin, 1973), subjects reported their attraction toward actual dating partners. Here again, results seem contradictory to a simple classical conditioning model, indicating increased attraction under relatively more adverse circumstances. It would seem, then, that results obtained using the bogus stranger method might not be readily generalizable to most situations involving actual *interpersonal* judgment under aversive conditions.

Validity of the Bogus Stranger Paradigm

If our reasoning up to this point is correct, the inconsistent results of those studies investigating the influence of negative situations on attraction pose a problem not for the classical conditioning model as a whole but only for the generality of one derivation from that model, which has received support and general acceptance because of the use of a particular limited methodology.

At this point it should be noted that the validity of the bogus stranger technique has been the subject of a great deal of debate in a different area of interpersonal attraction research, namely, in studying the relationship between similarity and attraction. Critics have suggested that results from such bogus stranger studies might not always generalize beyond the confines of the paradigm (Levinger, 1972; Murstein, 1971; Wright, 1971). In brief, the content of these arguments has been that results from observations of actual relationships will likely show a much weaker connection between similarity and attraction than that obtained using the laboratory paradigm. With regard to the connection between negative affect and interpersonal attraction, however, it would seem that the influence of negative environmental stimuli is not only weaker than one would expect on the basis of studies done within the bogus stranger paradigm but would actually tend to be *opposite* in its influence on actual interpersonal attraction, *even* within the confines of a short first encounter in a laboratory setting. In effect, while it may generally be profitable to view a target person as a neutral stimulus to which reinforcement value may be conditioned, that same other individual, *even if she or he is a complete stranger,* may actually take on a positive valence in threatening or aversive situations.

It is our contention that the data presented thus far seem, in themselves, to strongly support the resolution we have outlined. In order to control for the possible operation of other, perhaps less obvious, factors, however, we conducted an experiment in which subjects evaluated both bogus strangers and actual strangers under identical aversive conditions. It was predicted that contiguously presented aversive stimuli would have the effect of decreasing attraction toward the bogus stranger while increasing attraction toward a stranger who had been physically present with the subject.

Method

Subjects

Subjects were 66 undergraduate females enrolled in an introductory psychology course at Montana State University. They received credit toward their course grade for their participation. Subjects participated in groups of two. There was no theoretical reason for limiting the subjects to females. Given the necessity of having both subjects show up, females were chosen, because in our experience here they had been more reliable. Each member of a dyad came from a separate large introductory section. Four subjects (two dyads) were dropped from the experiment because they had prior acquaintance with their experimental partner, and two were dropped because of suspicion about the rated profiles. The remaining 60 subjects were equally divided into the high and low noise conditions (described below).

Procedure

Subjects arrived for an experiment on "environment and judgment." The two subjects arrived at

---

[2] Consistent with our own reasoning, Bell and Baron (1976) suggest that their failure to replicate the findings of Griffitt (1970) and Griffitt and Veitch (1971) may have been due to the fact that "any negative affect of high ambient temperature may have been neutralized by a positive feeling of 'shared suffering' " (pp. 28–29).

separate locations for any given experimental session and were brought (individually) to the experiment room. Here the experimenter introduced them, asked if they had prior acquaintance, and then explained:

> As the experimental title indicated, we're interested in the effects of environmental stimuli on judgment. We're particularly interested in the effects of environmental noise. You two will be in the high (low) noise condition.
>
> The first task you'll be working on is simply an attitude survey. We ask that you not discuss this with one another, since people are often strongly influenced by others on these things. We'll also be returning to a similar task later—so again, please do not discuss these with one another (all subjects complied with this request).

Noise manipulation. The experimenter turned on a noise tape at this point. Subjects in the aversive noise condition heard a tape that consisted of intermittent, unpredictable bursts of very loud noise—peaks were 95 dB (A)—determined to be highly aversive in preexperimental testing.[3] Subjects in the low noise condition heard the same tape played at a very low level (peaks were 32 dB).

Attraction ratings. After completing the 26-item attitude survey questionnaire, subjects were given a short filler task while the experimenter constructed bogus attitude surveys based on each subject's responses. Using a method based on Byrne's (1971) "method of constant discrepancy," a moderately similar profile was constructed for each subject (average discrepancy = 2 points on a 6-point scale). The experimenter then returned and explained:

> We'll be separating the two of you for the remainder of the experiment. I need one of you to come with me—it doesn't really matter which of you, since there's another speaker in the other room playing the same noise tape.

The experimenter always chose the subject to his right and in actuality took her to an adjoining room where the same condition noise tape was being played. After separating the subjects, the experimenter explained to each:

> This part of the experiment involves interpersonal judgment when only a small amount of information is available. You'll be rating a girl who was in a completely different experiment earlier this year and filled out an attitude survey similar to the one you've just completed. Please read the person's answers carefully and try to form an opinion about her.

The subject was given an attitude profile sheet with the name "Jean Haverland" on it. The other subject was given the same instructions, but was told that "you'll be rating (name of co-subject), the other girl in the experiment with you." Subjects were told that their ratings would remain "completely confidential" and were asked to give a "frank and honest judgment." Subjects who first rated the bogus stranger were then asked to rate the "other subject" and vice versa. In each case the subject received another profile of exactly the same degree of discrepancy, except that item directionality was varied. For instance, if the subject's responses to Items 8, 9, 10, and 11 were 3, 4, 4, and 3, respectively, one profile might read 1, 2, 6, and 5 on those items, whereas the other might read 5, 6, 2, and 1 (on sum, the mean discrepancy of each profile was identical).

For half the subjects, the "other subject" had indicated that she would shortly be leaving the state (in response to an item tapping attitudes about differential funding for the major rival branch of the state university system), whereas half of the subjects saw the same comment on the profile attributed to the bogus stranger. Order was randomized. Similar statements have been included in earlier research using this technique (Byrne, 1971) to lead the subject not to expect future interaction with the partner.

The noise tape (either aversive or control) was continued during the interpersonal judgment measures. The ratings were made on the standard Interpersonal Judgment Scale (Byrne, 1971). The "liking" and "desire to work" items were, in the typical fashion, summed to yield the major dependent variable. Following the ratings, the noise was terminated, and subjects were fully debriefed and thanked for their participation.

Predictions. It was expected that the results for the attraction measure would show an interaction of noise condition and type of stranger rated, indicating relatively more positive ratings of the other subject in the high noise condition, but an opposite effect for ratings of the simulated stranger.

Results

An initial $2 \times 2 \times 2$ analysis indicated no effect of the target person's intention to leave

---

[3] Thirty-two female subjects from the same population used in the experiment proper were exposed to either the high or low noise conditions while performing the initial task engaged in by experimental subjects (filling out the attitude questionnaire). They then responded to two questions designed to assess the aversiveness of the noise: "How annoying do you find this noise?" (0 = "not at all annoying"; 100 = "extremely annoying") and "How pleasant do you find this environment to be?" (−3 = "not at all pleasant"; +3 = "extremely pleasant"). Mean ratings on the first item were 67.87 and 31.67 for the high and low noise conditions, respectively, $F(1, 30) = 17.30$, $p < .001$. Similarly, the second item yielded mean ratings of −2.29 for the high noise and −.72 for the low noise conditions, $F(1, 30) = 14.27$, $p < .001$.

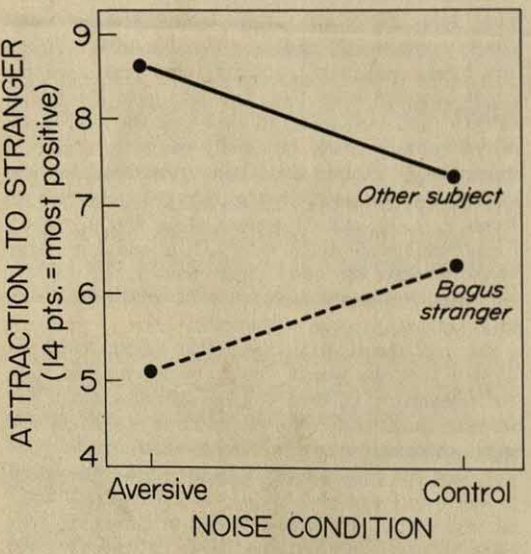

Figure 1. Attraction ratings as a function of noise condition and type of stranger rated.

the state nor any interaction of this factor with the central manipulation in the present study (all Fs < 1), and this variable will not be discussed further. Results are displayed in Figure 1 according to a 2 (between-groups : noise level) $\times$ 2 (within-groups : type of stranger) analysis of variance and indicate that our hypotheses were clearly supported, $F(1, 114) = 7.02$, $p < .01$, for this interaction. Ratings of the fictional stranger were, as predicted, significantly more negative in the aversive noise condition than in the low noise condition, $F(1, 56) = 4.80$, $p < .05$. Ratings of the other subject indicated that these were affected in the opposite direction by the noise manipulation, $F(1, 56) = 6.21$, $p < .03$. In addition, the overall main effect of the type of stranger indicated that other subjects were generally rated more positively than bogus strangers, $F(1, 114) = 62.11$, $p < .001$. The overall main effect of noise level was not significant, $F(1, 114) < 1$.

Discussion

Our results are clear in supporting the hypothesis that, under negative conditions, the bogus stranger method yields results that are contradictory to those obtained using "real" others as target persons, even in a short-term laboratory encounter. The results we obtained for bogus strangers are directly in line with those obtained in prior studies using this method (e.g., Griffitt, 1970; Griffitt & Veitch, 1971), while our results for ratings of contiguously present others are consistent with the general findings of previous studies using this method (e.g., Byrne et al., 1975; Dutton & Aron, 1974; Latané et al., 1966).

A recent paper by Rotton, Barry, Frey, & Soler (1978) reported results that are compatible with those of the present investigation. In their first experiment, these authors failed to find the predicted decreases in attraction for a stranger as a function of unpleasant odors. In this case, however, the attitude profile rated by the subject was presented as having been filled out by another subject in an adjoining room (and presumably "sharing stress" with the subject). In Rotton et al.'s (1978) second experiment, however, it was made clear to the subjects that they were alone in the situation and that the person being rated was not a fellow participant. In this study, unpleasant odor led to significant decreases in attraction for the rated other. These authors concluded that "negative affect generalized onto liking of other persons in the environment" (p. 67) but added the qualification that "air pollution reduces attraction only when a person is isolated" (p. 68). We would argue, of course, that the results of Rotton et al.'s first study are more likely to generalize to actual interpersonal encounters, since attraction would seem to be rarely developed when one is in isolation.

Thus, the use of the bogus stranger technique in the present line of investigation is even more strongly subject to criticisms of its validity than is the case in similarity–attraction research (Levinger, 1972; Murstein, 1971; Wright, 1971), where the general accuracy of the relationship, if not its intensity, seems to be ecologically valid (Byrne, Ervin, & Lamberth, 1970; Clore & Byrne, 1974).

Theoretical Considerations

While our results oppose one specific deduction from the classical conditioning model—that persons come to dislike strangers whom they meet under aversive circumstances—they

can in fact be seen to be in essential agreement with the overall reinforcement model. As we stated earlier, the failure of the simple classical conditioning model in this instance may stem from the fact that other persons function as *generalized reinforcers* under aversive circumstances (Back & Bogdonoff, 1964; Kenrick & Cialdini, 1977; Schachter, 1959; Wrightsman, 1960), and their negative reinforcement value (as potential reducers of aversive arousal) can generally be expected to neutralize or outweigh any immediate generalization of negative affect. Thus, we remain in agreement with the basic assumptions of the Clore and Byrne (1974) model, while calling into question certain lower level deductions from that model.

The present data suggest an important conceptual qualification on the simple affective generalization model, however. Certainly mere contiguity with a negatively toned context is not sufficient, in itself, to produce disliking for another. Instead, it seems necessary to consider the subject's cognitions to explain at least part of the present experiment's pattern of results. Subjects' ratings of their fellow subject showed a pattern that did not follow from simple contiguity assumptions, but instead seemed to indicate an active and discriminating attributional analysis of the situation. Such a consideration of cognitive information processing is, of course, compatible with recent statements of the reinforcement–affect model of attraction (Clore & Byrne, 1974).

Although the suggested negative reinforcement model is consistent with prior literature and seems a plausible explanation of the present results, it should be noted that we do not directly demonstrate the reduction of aversive arousal in our data. It might be the case, for instance, that attraction for the physically present other in the aversive condition was not increased because of the reduction (or even anticipated reduction) of aversive arousal, but instead because the experience of shared stress may have led to an increased perception of similarity or "unit relationship" with the fellow subject. Since the subjects had a great deal of information relating to the target person's attitudes on controversial positions, it seems to us unlikely that this one additional cognitive input would greatly alter the extent to which the target was seen as similar/dissimilar, but such an account cannot be ruled out, particularly since "shared stress" was certainly a salient issue in this case. Further research investigating the mediator of these effects would be worthwhile.

Future research is also needed to determine which components of the other subject's presence mediate the demonstrated increases in attraction under aversive circumstances. For instance, subjects in the aversive condition may have engaged in higher levels of mutual eye contact than those in the low noise condition. Research by Morris et al. (1976) supports the suggestion that aversive conditions do produce differential patterns of interaction between subjects, although the research of Rotton et al. (1978), discussed above, suggests that the simple knowledge that the other is sharing a stressful experience with oneself may sometimes be sufficient to produce attraction.

When Will Negative Affect Decrease Attraction?

The major point of these data is to suggest the severe ecological limitations of those earlier findings (e.g., Griffitt, 1970; Griffitt & Veitch, 1971), which social psychologists have widely accepted to mean that "any event that arouses a negative emotional state may create a temporary dislike for whoever is nearby" (Tedeschi & Lindskold, 1976, pp. 455–456). In assessing the effect of simple negative arousal on interpersonal attraction, results from studies using the bogus stranger paradigm would seem to explain only a rather limited range of situations (i.e., those in which one is evaluating another person who is not physically present). Whenever the object person is present, negative conditions would be expected to result in rather different effects on attraction.

It should be noted here that we are dealing only with the case of impersonal aversive or threatening environmental stimuli, from which it has been determined that individuals do

in fact seek solace in the company of others (Burlingame & Freud, 1943; Marshall, 1951; McIntyre, 1971; Sarnoff and Zimbardo, 1961; Schachter, 1959; Wrightsman, 1960). We would not, for instance, expect the present results to hold in situations involving potential interpersonal embarrassment, where the presence of others has punishment, as opposed to reinforcement, value. For instance, Sarnoff and Zimbardo (1961) found that whereas 95% of their subjects who expected painful electric shocks wished to wait in the company of others, the majority of those expecting to perform potentially embarrassing behaviors expressed a desire to wait alone. Consistently, Griffitt and Guay (1969) found that their subjects showed decreased attraction for others who were present when the subject received esteem-damaging feedback (negative creativity ratings), even when that other was not personally responsible for the feedback. On the other hand, Jacobs, Berscheid, & Walster (1971) found that females were more attracted to a male they met after receiving self-esteem-lowering feedback. In this case, however, the male was not present during the receipt of the feedback, but served to repair the subject's damaged self-esteem by expressing romantic interest in her.

Finally, it would be expected that other persons who are themselves *directly responsible* for inducing negative affect in an individual will come to be disliked, and there is an abundance of data to support this supposition (e.g., Burnstein & Worchel, 1962; Byrne & Rhamey, 1965; Griffitt & Guay, 1969; Hendrick & Taylor, 1971; Sigall & Aronson, 1969).

Blood Donation and the Foot-in-the-Door Technique: A Limiting Case

Robert D. Foss
Department of Sociology and Anthropology
Western Carolina University

Carolyn B. Dempsey
University of Tennessee, Knoxville

Three experiments testing the effectiveness of the foot-in-the-door technique for recruiting blood donors consistently failed to demonstrate that this procedure influences either verbal or behavioral compliance, suggesting that the generality of the foot-in-the-door phenomenon is limited. Experiment 1 attempted to demonstrate that an earlier failure of this technique was due to poor operationalization rather than to the magnitude of the critical request or to the invalidity of the phenomenon, but it failed to do so. Experiment 2, designed to more closely resemble other foot-in-the-door studies by using telephone contacts and an initial request for persons to answer questions, was conducted to examine other possible explanations for the two previous failures. This experiment also failed to show any foot-in-the-door effect. Experiment 3 was a conceptual replication of Experiment 2 but used personal contacts. One apparent foot-in-the-door effect emerged in this case, but it was more likely due to a factor other than the experimental treatment. It is concluded that although the foot-in-the-door procedure may indeed influence verbal compliance with requests for minimal forms of aid, it probably will not significantly affect people's willingness to comply with more substantial requests involving behaviors that are psychologically costly to perform.

A number of recent investigations of the effects of compliance with a small request on subsequent compliance with a more substantial request (the "foot-in-the-door" phenomenon) suggest the possibility of a direct and exciting application of social psychological knowledge to practical matters. It has bee shown repeatedly that persons who are i duced to comply with a small request a much more likely to comply with a subs quent (critical) request of greater magnitu than would be the case if there had been preliminary request (Cann, Sherman, & Elke 1975; Freedman & Fraser, 1966; Pliner, Har Kohl, & Saari, 1974; Seligman, Bush, Kirsch, 1976; Snyder & Cunningham, 1975 The apparent reason for this effect is th initial compliance alters a person's self-pe ception, and as a result, the person, seei himself/herself as more of a helper than pr viously, is more likely to help a stranger whe asked (Snyder & Cunningham, 1975) merely when the situation presents its (Uranowitz, 1975).

One clear implication of these findings that various service organizations such as t American Cancer Society, the American Hea Association, the American Red Cross ought be able to make good use of this technique

The authors wish to express their appreciation to Morris White of the Asheville Regional Blood Center of the American Red Cross and Thomas Brinson of the MEDIC organization for their cooperation and assistance on this project and to Gail Whisenant for assisting with data collection in Experiment 1. A special note of appreciation is also due Anthony Greenwald for his careful consideration and comments on an earlier version of this article.

Carolyn B. Dempsey is now at the Special Projects Office, Eastern Band of the Cherokee Indian.

A report of Experiment 1 was presented at the annual meeting of the Southeastern Psychological Association, Hollywood, Florida, May 1977.

induce compliance with their requests for aid in their respective tasks. In fact, Pliner et al. (1974) were able to nearly double the number of contributors to the Cancer Fund in a suburban neighborhood of Toronto, Canada, by using this technique. However, with this exception and one other, all studies of the foot-in-the-door phenomenon have used rather trivial requests, and a large number have employed a single research paradigm, which is to make requests over the telephone for persons to answer varying numbers of questions.

When the foot-in-the-door technique was used in a different and more realistic field setting in an attempt to increase blood donations, it failed (Cialdini & Ascani, 1976). In that study, the second request was made immediately after the first, which may not have allowed time for a person's self-perception to be sufficiently altered by compliance with the initial request. However, Cann et al. (1975) have shown, albeit in the somewhat artificial telephone interview paradigm, that timing of the second request apparently is not crucial for the foot-in-the-door effect to emerge. Therefore, it may simply be that moving from a rather trivial request such as answering questions in a telephone interview or donating money to a charity [1] to a more substantial one such as asking for a blood donation provides more of an obstacle than the foot-in-the-door technique can overcome.

Given that several studies of helping have documented a substantial rate of attrition between volunteering to do something and actually doing it (cf. Gross, Wallston, & Piliavin, 1975; Kazdin & Bryan, 1971), the generalizability of the foot-in-the-door phenomenon to settings in which such a technique might have some practical utility is further questioned; only Pliner et al. (1974) and Cialdini and Ascani (1976) have studied actual behavioral compliance with the critical request.

The present studies were designed to clarify some issues that are of importance for the practical application of the foot-in-the-door phenomenon. In particular, it would be useful to know (a) whether the effect does reliably occur with respect to overt behavior as well as verbal behavior, (b) whether the effect extends to other than question-answering behavior, and (c) how strong the effect is. Since Cialdini and Ascani's (1976) negative results amount to an acceptance of the null hypothesis, a replication of this result would be desirable before much confidence is placed in it. Therefore, the present series of experiments also used the foot-in-the-door technique in an attempt to increase blood donations during the visit of a bloodmobile to a university campus. Experiment 1 is a modified replication of Cialdini and Ascani's experiment in which timing of the critical request was manipulated to see whether it was the timing or the magnitude of the critical request that was more likely responsible for the failure of the foot-in-the-door effect to materialize in that study.

Experiment 1

Method

Research participants were 76 dormitory residents at a small, rural university. For each hall in each of the 10 dormitories on campus, a room number was randomly selected. Two female experimenters individually approached selected rooms between 6 p.m. and 10 p.m. and made the following initial request to the person answering the door:

> Hi, my name is _____, and I am working as a volunteer for the Red Cross. Our bloodmobile is to be here next week [on Tuesday] [tomorrow] and Wednesday from 12:00 to 6:00 p.m. Would you help us advertise its visit by putting this poster on your door?

Persons who agreed were given a poster that stated the time, place, and date of the bloodmobile visit and that contained the American Red Cross logo. The experimenter then took the subject's name and recorded his/her sex. All persons were thanked for their help, or if they did not cooperate, they were thanked just for listening. If no one answered the door of a preselected room, another room on the same hall was randomly selected and approached.

Timing between initial and critical requests was manipulated by making the initial request on the Wednesday (5-day delay) or Friday (3-day delay) of the week preceding the bloodmobile visit or on

---

[1] Forty-eight percent donated with no prior request in the Pliner, Hart, Kohl, and Saari (1974) study, indicating that donating small amounts of money ($M < \$1$) to a good cause is a behavior people are not terribly hesitant to engage in.

Table 1
Percentage of Verbal and Behavioral Compliance by Experimental Condition—Experiment 1

Compliance	Condition (%) 5-day delay	3-day delay	No delay	Control	χ^2	p
Verbal compliance						
Recontacted sample	53 (9 of 17)	54 (7 of 13)	55 (11 of 20)	53 (10 of 19)	.046	>.80
Behavioral compliance						
Recontacted sample	18 (3 of 17)	38 (5 of 13)	25 (5 of 20)	26 (5 of 19)	1.672	>.50
Entire sample	14 (3 of 22)	33 (5 of 15)	25 (5 of 20)	26 (5 of 19)	2.095	>.50

Note. *N*s are given in parentheses. Data for verbal compliance are for 69 persons who were successfully contacted for both the initial and critical request (recontacted sample). Data for behavioral compliance are reported for these persons (recontacted sample) and for these persons plus 7 persons who could not be contacted for the critical request but whose behavioral compliance could nevertheless be determined (entire sample).

the Monday evening (no delay) prior to the bloodmobile visit. The critical request was then made on the Monday evening preceding the bloodmobile visit.

In the 5-day and 3-day delay conditions, persons were recontacted by a different experimenter who also presented herself as a Red Cross volunteer and asked if the person would be willing to donate a pint of blood.

In the no-delay condition, after the person had agreed to the initial request to display the poster, the experimenter continued with the following request: "There is one other thing you can do for us. We are asking students to donate one pint of blood tomorrow and I wondered if you would volunteer to donate?" In the control condition, persons were simply contacted for the first time on the Monday evening preceding the bloodmobile visit and asked if they would donate. A list of the names of all persons who appeared at the donation center and either donated or were deferred for medical reasons was obtained from the American Red Cross. This list was used to determine how many persons in each experimental condition actually complied behaviorally with the critical request as well as how many of those in each condition were previous blood donors.

Results

There were no sex differences for verbal compliance, with 55% of males (18 of 33) and 53% of females (19 of 36) verbally agreeing to donate nor were there any differences for behavioral compliance, with 27% of males (9 of 33) and 25% of females (9 of 36) actually appearing at the donation center.[2] Therefore, male and female data were combined for the following analyses.

Verbal compliance. Table 1 indicates that there was practically no variation in compliance across conditions, and the differences did not approach statistical significance, $\chi^2(3) < 1$. Combining all experimental conditions, the overall verbal compliance was 54% (27 of 50), which is virtually identical to the 53% compliance rate in the control condition, $\chi^2(1) < 1$.

Behavioral compliance. It was expected that behavioral compliance would be substantially less than verbal compliance, and this turned out to be the case (see Table 1), with only about half of those who verbally complied actually showing up to donate. Again there were no significant differences in compliance rates between conditions, $\chi^2(3) = 1.67$, $p > .50$. The compliance rate in the combined experimental conditions was 26% (13 of 50), which is identical to the compliance rate in the control condition.

In an attempt to determine why behavioral compliance was so much lower than verbal compliance, information about the previous donation history of all persons who verbally complied was obtained from local Red Cross records. As Table 2 indicates, this one bit of information is vital in explaining differences in behavioral compliance among those who verbally complied. Of those who had donated

[2] Seven persons could not be recontacted for the critical request (five in the 5-day delay condition and two in the 3-day delay condition).

before, 82% (14 of 17) carried through on their verbal commitment, whereas only 21% (4 of 19) of those who had never donated before did so, $\chi^2(1) = 11.15$, $p < .001$ ($\phi = .61$).[3] Thirty-seven percent of the variation in behavioral compliance in this group was accounted for by donation history. Furthermore, it is evident from the table that this relationship between donation history and behavioral compliance holds up within both the experimental condition, $\chi^2(1) = 7.96$, $p < .005$ ($\phi = .63$) and the control condition (Fisher's exact test, $p = .083$, $\phi = .65$), suggesting that the experimental treatment had no effect on the relationship between these variables.

Table 2
Behavioral Compliance of Previous Donors and Previous Nondonors—Experiment 1

	Condition			
	Experimental[a]		Control[b]	
Compliance	Donor	Non-donor	Donor	Non-donor
Yes	9	4	5	0
No	1	12	2	3
Total	10	16	7	3

Note. This table includes only those persons who verbally complied with the request to donate blood plus two who failed to verbally comply but donated anyway.
[a] In the experimental condition, $\chi^2_{(1)} = 7.96$, $p < .005$, $\phi = .63$.
[b] In the control condition, Fisher exact, $p = .083$, $\phi = .65$.

Discussion

The present results call into question the external validity of the foot-in-the-door phenomenon. While it previously appeared that Cialdini and Ascani (1976) may not have obtained the usual effect because of an improper operationalization of the technique, the present study rules out this interpretation and leaves us with the suspicion that this phenomenon may not be robust enough to affect those behaviors that people are initially somewhat hesitant to engage in. It is well-known that most people, if they have never donated blood before, are quite reluctant to do so (American Red Cross, undated). On the other hand, examining the amount of compliance obtained in control conditions of previous foot-in-the-door studies, we find that anywhere from 17% (Freedman & Fraser, 1966) to 50% (Cann et al., 1975) of the people who were simply asked initially to engage in the criterion behavior were willing to do so. This suggests that none of these behaviors were particularly noxious in the first place. (Indeed, with the exception of the Freedman & Fraser experiments, the criterion behaviors were quite minimally inconveniencing or costly.)[4]

Another possible reason for the failure of the foot-in-the-door effect to materialize for Cialdini and Ascani (1976) as well as in the present experiment has to do with situational factors that may have intervened to prevent any alteration in self-perception as a result of compliance with the initial request. If there is strong external justification for a behavior, that behavior is likely to be dis-

[3] All chi-square values reported with 1 degree of freedom are corrected for continuity.

[4] It might be argued that the 32% verbal compliance rate obtained by Cialdini and Ascani (1976) and the 53% verbal compliance in the present study provide evidence that people are also fairly willing to donate blood; however, such a conclusion is not justified. The baseline compliance rate in blood donation studies is elevated by the presence in the sample of previous donors, who are much more likely to agree to give blood than persons who have never donated (Foss, Note 1). Consequently, this baseline rate is not an accurate indicator of the reluctance of people in general to engage in this particular criterion behavior.

In the present study, both the 53% verbal compliance and the 26% behavioral compliance are abnormally high and, in fact, are much higher than those reported by Cialdini and Ascani (1976). This can be accounted for the fact that there is a well-organized, continuing effort to obtain blood donations on the campus at which the present study was conducted, providing a climate of normative support for this activity (cf. Barton, 1969), and many students have donated previously. Indeed, of those in the present experiment who verbally complied, 47% were previous donors, and 78% of those who actually donated were previous donors. In a subsequent study (Experiment 2) conducted on another campus at which the normative climate is not so conducive to blood donation, verbal compliance was only 25% and behavioral compliance a mere 3%.

counted rather than taken as an indication of a person's character (Bem, 1972; Kelley, 1971). It is quite possible that the initial request (to help advertise the presence of a mobile blood-collection unit on campus) was for such a good cause that people perceived a great deal of external justification for doing so—"Sure I'll do that, anybody would."—and, hence, did not attribute "helper" characteristics to themselves subsequent to the initial behavior.

There is yet another possible explanation for the failure of the foot-in-the-door technique to influence blood donation. It may be that size of the initial and critical requests must be correlated such that for a larger critical request, one must use a more substantial initial request. Seligman et al. (1976) found this to be the case using the telephone interview paradigm, and it is plausible that one's self-perception will be more strongly influenced by an initial agreement to a moderate request than to a small request. Therefore, it may still be possible to develop practical applications of this technique in areas in which human aid or assistance are needed but in which people are reluctant to provide such services. However, by having to increase the magnitude of the initial request, one is of necessity decreasing the number of persons who can be subjected to the technique, because of the decreased likelihood of compliance with the initial request. One of the main appeals of the foot-in-the-door technique is the possibility that even the most trivial of initial requests may be sufficient to increase subsequent compliance. However, if this is not the case, and considering the substantial effort that would be necessary to carry out a recruitment project using this technique, the minimal payoffs may not be worth the effort. Nevertheless, in the interest of a better understanding of this phenomenon and to provide a more thorough specification of relevant parameters, two further experiments were conducted.

Experiment 2

A second study was conducted to examine the possibilities suggested earlier (a) that because of the compelling nature of the request used, altered self-perceptions might not be induced or (b) that the initial request was not large enough to alter self-perceptions sufficiently to influence compliance with so large a request as donating blood. Contacts were made by telephone, as has been the case in most other foot-in-the-door studies, and a condition similar to that typically used in such studies was added to approximate more closely the procedures used in studies in which this technique has been successful. This experiment was also conducted in connection with a 2-day bloodmobile visit to a university campus.

Method

Research participants were 135 dormitory residents at a large, urban university. Participants were randomly selected from a listing of dormitory residents and assigned to one of three experimental conditions or to a control group. Persons in the experimental conditions were then contacted by phone on either Wednesday or Thursday evening between 6:00 p.m. and 9:30 p.m. and were asked if they would be willing to do one of the following tasks, depending on the condition to which they had been assigned:

Routine initial request. Subjects were asked to answer a few questions about blood donation. If they agreed, five questions were asked, including whether they had ever donated, and they were thanked for their cooperation.

Poster request. Subjects were asked to allow the blood organization to put a poster on their dormitory room door to advertise the bloodmobile visits. If they agreed, they were asked the location of their room, their age, and whether they had ever donated blood. They were then thanked for their cooperation.

Large initial request. Subjects were asked to recruit four friends to donate blood as part of a new approach to donor recruitment being tried during the upcoming bloodmobile visit. If they agreed, they were simply told to contact four friends, inform them that the bloodmobile would be on campus the following Monday and Tuesday, and ask them to donate. Participants were then asked their age and whether they personally had ever donated. They were then thanked for their cooperation.

On the following Sunday and Monday nights (3–5 days later), all experimental subjects and all members of the control group were called by a different person, who informed them that the bloodmobile would be on campus for two days and who asked them if they would be willing to donate a unit of

Behavioral compliance						
Entire sample	5 (2 of 41)	4 (1 of 28)	0 (0 of 36)	3 (1 of 30)	—	—

Note. *N*s are given in parentheses. Data for verbal compliance are for 110 persons who were successfully contacted for both the initial and critical request. Data for behavioral compliance are for these persons plus 25 others who could not be contacted for the critical request but whose behavioral compliance could nevertheless be determined (one of the donors in the routine condition was in this group).

blood.[5] Persons who agreed were told of the time and place and were reminded to eat a good meal before coming to donate.

To summarize, there were three experimental conditions ranging from a small initial request, which is the type normally used in foot-in-the-door research, to a moderate initial request that was essentially identical to that used in Experiment 1, to a large initial request that should have a greater effect on self-perceptions if persons agree to it. There was also a control condition with no initial request.

Results

Verbal compliance. Twenty-five persons could not be recontacted for the critical request (7 each in the poster and large request conditions, 11 in the routine condition), hence, for these people the amount of verbal compliance is unknown.[6] Persons who said they might donate were classified as refusals. Table 3 shows the amount of verbal compliance both before and after persons who reported they were previous donors were removed from the analysis. In neither case was the overall chi-square significant. In both instances the greatest amount of verbal compliance was obtained in the large initial request condition, but in neither case was this significantly different from the control condition. Finally, combining the experimental groups, the overall compliance rate was 26% (21 of 80), which does not differ from the 20% compliance obtained in the control condition, $\chi^2(1) < 1$. With previous donors removed, the combined compliance rate was 25% (18 of 71), which is not significantly different from the 22% compliance in the control condition, $\chi^2(1) < 1$.

Behavioral compliance. There was virtually no behavioral compliance, with only four persons donating, one of whom had not been successfully contacted for the critical request. This result underscores one conclusion of another study of blood donation that personal contact is a far more effective recruitment technique than telephone contact (Ford & Wallace, 1975). Unfortunately, the extremely small amount of behavioral compliance obtained in the present study (3%) precludes a definitive test of the possible effects of differing initial requests, although the failure of effects to materialize with verbal com-

[5] All callers were unaware of the hypothesis being tested. Although some persons in the large request condition may have failed to behaviorally comply with the initial request, only 2 persons (poster condition) would not agree to the initial request. Due to the time pressures generated by having to contact 135 persons within two fixed 3½-hour time periods, these 2 persons were not recontacted for the critical request but were included in the analyses where possible (i.e., behavioral compliance).

[6] This is a disturbingly large attrition rate; however, there is little reason to believe that these persons differ in any important way from those we could successfully recontact. Because of the logistics of contacting a large number of persons during a relatively short time period, only a limited number of call backs were possible, and these persons simply were not in when we called.

pliance suggests once again that the foot-in-the-door technique simply does not work with blood donation. Nevertheless, a third experiment was conducted in a further attempt to determine if it might yet work under the right circumstances.

Experiment 3

Method

This experiment was conducted on the same campus as Experiment 1, 9 months later, during a different academic year, and again in connection with a bloodmobile visit to campus. Procedures were similar to those in Experiment 2, but dormitory rooms rather than individuals were sampled to maximize the sample size with which we would ultimately be able to make two contacts. Five or 6 days prior to the bloodmobile visit, research participants were contacted in person by an experimenter who delivered one of three initial requests to whomever answered the door, depending on the condition to which the room had been assigned:

Routine initial request. Subjects were asked to answer six or seven questions about their knowledge of and experience with blood donation.

Poster request. Subjects were asked to put a poster on their door advertising the bloodmobile visit to campus.

Large initial request. Subjects were asked to recruit four of their friends to donate blood.

Persons who agreed to the request were asked the questions, given the poster, or told how to recruit friends as in Experiment 2. They were then asked their names and whether they had ever donated blood. For purposes of secondary analysis, a record was kept of all persons who reported conditions that would legitimately disqualify them from donating blood (chronic illness, underweight, temporary illness, etc.).

On the evening preceding the bloodmobile visit, all persons who had received an initial request and persons in the control group were contacted by a different experimenter (who feigned ignorance of the earlier contact by an experimenter)[7] and asked to donate blood the following day. Those who agreed to donate were reminded of the time and place and to eat a good meal before coming to donate. Everyone was thanked for his/her time, even if he/she had refused to donate.

Results

Of the 127 persons initially contacted, 95 were successfully recontacted and asked to donate blood. In addition, 36 persons in the control group were contacted for the first time and asked to donate. Since there were no significant differences between males and females for verbal compliance (36% vs. 39%) or for behavioral compliance (12% vs. 14%), data were combined for the following analyses.[8]

Verbal compliance. Although there were some moderate variations in verbal compliance across conditions (see Table 4), these did not approach statistical significance, $\chi^2(3) = 2.30$, $p > .50$. Compliance was greatest in the poster condition (44%), although it did not differ significantly from the control condition, $\chi^2(1) = 1.27$, $p > .20$. The 40% (38 of 95) compliance rate among combined experimental conditions also did not differ significantly from the control condition, $\chi^2(1) < 1$.

Behavioral compliance. Since 32 persons could not be recontacted for the critical request (8, 11, and 13 in the routine, poster, and large request conditions, respectively), two sets of analyses were conducted. Although these persons were not directly asked to donate, they were in experimental conditions that, in view of the processes apparently involved in the foot-in-the-door phenomenon, should have made them more likely to do so when the opportunity presented itself (cf. Uranowitz, 1975). On the campus at which this study was conducted, almost everyone knows when the bloodmobile is on campus and, therefore, is aware of the opportunity to donate.

First, in the recontacted sample (see Table 4), which provides the easier task for the foot-

---

[7] Both verbal and behavioral compliance rates were substantially higher in Experiment 1. This finding appears to have been due primarily to the fact that Experiment 3 was conducted during the winter, in the midst of a flu epidemic, whereas Experiment 1 was conducted in the spring.

[8] Although recruiters were initially blind to the respondent's experimental condition, those in the poster condition were easily recognized as such when the recruiter approached the room. This is unfortunate but is probably not serious, since recruiters were unaware of the specific nature of the hypotheses being tested. Furthermore, the crucial question became (see below) whether any or all experimental conditions differed from the control group rather than whether there were any differences between experimental conditions.

Table 4
Percentage of Verbal and Behavioral Compliance by Experimental Condition—Experiment 3

Item	Condition (%)				χ^2	p
	Routine request	Poster request	Large request	Control		
Verbal compliance						
Recontacted sample	43 (16 of 37)	44 (14 of 32)	31 (8 of 26)	31 (11 of 36)	2.30	>.50
Behavioral compliance						
Recontacted sample	16 (6 of 37)	31 (10 of 32)	12 (3 of 26)	6 (2 of 36)	8.83	<.05
Entire sample	13 (6 of 45)	23 (10 of 43)	8 (3 of 39)	6 (2 of 36)	6.79	<.08

Note. *Ns* are given in parentheses. Data for the recontacted sample are for 131 persons who were successfully contacted for both the initial and critical request. Data for the entire sample also include 32 persons who could not be contacted for the critical request but whose behavioral compliance could nevertheless be determined.

in-the-door technique, there was a significant overall effect, $\chi^2(3) = 8.83$, $p < .05$; this was accounted for by the poster condition, which differed significantly from the control condition, $\chi^2(1) = 6.03$, $p < .02$. Neither of the other experimental conditions differed significantly from the control group. The combined experimental conditions differed from the control group at a marginal significance level (20% vs. 6%), $\chi^2(1) = 3.05$, $p < .09$, but again this is due primarily to the contribution of the poster condition.

For the entire sample, behavioral compliance in the experimental conditions was again somewhat higher than in the control condition, and the overall effect approached conventional levels of statistical significance, $\chi^2(3) = 6.79$, $p < .08$. The poster condition accounted for this effect and was significantly different from the control condition (23% vs. 6%), $\chi^2(1) = 3.49$, $p < .06$, whereas neither of the other two experimental conditions differed significantly from the control group. It should be pointed out that none of the 32 persons who were not recontacted actually donated, and it is arguable that the only fair test of the foot-in-the-door effect is the previous one involving only those contacted for both the initial and critical requests.[9]

Donation history. Among those persons who reported having donated previously, 59% (23 of 39) agreed to donate and among those who had not donated previously 30% (25 of 83) agreed to donate; $\chi^2(1) = 8.09$, $p < .01$.[10] Actual donation was also more common among previous donors (24%, 13 of 54) than among persons who had never donated (8%, 8 of 100), $\chi^2(1) = 6.39$, $p < .02$.

In the present experiment, previous donation history did not play such a strong role in determining whether persons who agreed to donate would actually do so as it did in Experiment 1. Nearly half (48%) of those who agreed to donate were previous donors, and of those, 39% actually donated, whereas 28% of those who agreed to donate but were not previous donors actually did so, $\chi^2(1) < 1$. Still, donation history is an important determinant of behavioral compliance, with those who have donated before three times as likely to donate as those who have not previously done so.[11] In the present experiment,

[9] A third set of analyses was conducted after excluding the 44 persons who reported a legitimate medical excuse for not donating, as well as the 32 persons not recontacted. This altered the percentages, but the same pattern of results as in the above analyses emerged for both verbal and behavioral compliance.

[10] Because of an oversight, information about donation history was not obtained from nine persons in the control group.

[11] In this study, information on donation history was obtained from the persons themselves, whereas in Experiment 1, it was obtained from actual records. It is possible that some persons felt a need to deceive us about their donation history and, therefore, that the results of this analysis are less reliable than those from Experiment 1.

previous donors constituted only one third (35%) of the sample, yet nearly two thirds (62%) of the donations were made by persons who had previously donated.

General Discussion

Since the experiments reported here primarily provide confirmation of a null hypothesis, a brief discussion of methodological issues surrounding this procedure is in order. Traditionally, in social psychology, experimental results that confirm the null hypothesis have been viewed with more than a little skepticism—often with good reason (Aronson & Carlsmith, 1968). Even if a study is well designed and well executed, one plausible alternative explanation of experimental results that confirm a null hypothesis is that the statistical test used may not have been powerful enough to detect a true effect. Thus, conventional canons of research dictate that very large samples are necessary to effectively test a null hypothesis.

The samples in the present study clearly are not particularly large, averaging about 31 persons per condition, which leaves open the possibility that the foot-in-the-door technique does indeed have an effect on compliance with requests to donate blood, but the effect is too small to detect with such small sample sizes. However, the purpose of the present studies was not the traditional one of examining a theoretical proposition but rather to examine the utility of a phenomenon in practical application. In such a situation, we are not particularly interested in small effects, real though they may be. Even though a compliance-inducing procedure might have the (statistically reliable) effect of increasing compliance by, say, 25% over normal procedures (an effect that would not be detected with a moderate sample size), this might very well be too small an effect to be of value in practical applications.[12] In organizational donor recruitment programs, cost–benefit analyses must be conducted, and on balance, procedures that produce real but small effects are not feasible unless they involve essentially no extra effort or expense to put into practice. To this we would add that in the present series of experiments, there is little evidence to suggest that there is even a small foot-in-the-door effect that would have been detected with larger sample sizes. The fluctuation in compliance rates across experiments and conditions appears to be essentially random.

In the three experiments conducted, comprising a total of nine experimental groups evaluated on two dependent measures each, only one foot-in-the-door effect occurred (Experiment 3, poster condition, behavioral compliance). The fact that this effect occurred in a condition that had no discernible effect in several other comparisons in Experiments 1 and 2 and that a behavioral compliance effect occurred in a condition in which there was no verbal compliance effect was somewhat puzzling. Further examination of the data yielded an explanation for this result. It was discovered that this one condition contained a substantially larger proportion of previous donors than any other condition (47% vs. 28%, 29%, and 37% in the routine, large request, and control conditions, respectively). Given the much stronger inclination of previous donors to donate, this provides a more parsimonious explanation of the greater behavioral compliance in this condition than does the foot-in-the-door explanation.

Given the consistent failure across three experiments to find a foot-in-the-door effect, despite different procedures (both telephone and in-person requests), study of different populations (urban and rural universities), and testing some of the most plausible alternative explanations for the initial failure, the only reasonable conclusion we are left with is that the foot-in-the-door technique does not work with blood donation. It appears that this behavior is too costly for a slightly altered self-concept, which the foot-in-the-door procedure presumably produces, to influence a person's willingness to donate.

---

[12] Assuming a 12% rate of compliance with a straightforward request to donate blood (based on control groups of studies in which persons were personally asked), a 25% increase above that would amount to only 3% more donors, which would hardly justify the expense of doubling the number of personal contacts in order to bring about the foot-in-the-door effect.

The present series of experiments provides evidence that the power of the foot-in-the-door technique for practical applications may have been overstated. Two of the most comprehensive and popular recent social psychology textbooks maintain that the effectiveness of this technique is well established (Baron & Byrne, 1977; Wrightsman, 1977). However, although the existence of the foot-in-the-door phenomenon is well documented, its utility in practical applications is not, with only a single study demonstrating an effect on behavioral compliance with a request for a meaningful form of aid. The present series of failures, in addition to at least two others (Cann, 1975; Cialdini & Ascani, 1976), combined with the shortcomings of other studies previously mentioned, suggest that this technique may be of only limited value to organizations seeking ways to increase compliance with their requests for aid.

We suggest that at least part of the reason that the misconception about the power and practical usefulness of this technique has developed is because of the characteristics of the research publication system, which discourage the submission and acceptance for publication of studies that report negative results, that is, those studies that support the null hypothesis (Greenwald, 1975). Such biases against accepting the null hypothesis are particularly serious when results of social psychological inquiry are likely to be rapidly applied. If only positive findings emerge, a very misleading conception of a phenomenon can develop, and this appears to be precisely what has occurred with the foot-in-the-door phenomenon. The technique does appear to work well in some fairly limited instances, but the limitations have not been spelled out. The present series of experiments is a first step in the direction of identifying the crucial parameters that influence if, when, and perhaps how this technique works. Clearly, much remains to be done in order that future reports on the foot-in-the-door technique can be accompanied by appropriate cautionary remarks detailing the limitations of this procedure.

One final point is worth mentioning. Although the present series of experiments demonstrates convincingly that the foot-in-the-door effect does not influence blood donation, some caution should be exerted in interpreting these findings. On the basis of this single series of experiments plus one other (Cialdini & Ascani, 1976), it would be risky to conclude that all costly behaviors are resistant to the foot-in-the-door phenomenon, although the implication is certainly there. In some ways, blood donation is perhaps an unusual form of helping. For example, previous donation is an extremely powerful factor in present behavior, which is primarily a reflection of the irrational fears people have about donating blood (cf. Foss, Note 1). On the other hand, it would be equally unwise to attempt to explain away the present results as being due to the peculiar nature of blood donation. Other behaviors such as donation of organs, bone marrow, and large amounts of time or money have equally high costs (of varying sorts) and are also behaviors that a given proportion of any population simply cannot engage in because of physical or other unalterable limitations. Finally, if blood donation were also resistant to other, thoroughly documented, forms of social influence, we would be justified in concluding that the current results tell us more about blood donation than about the foot-in-the-door phenomenon. However, blood donation is quite susceptible to various other forms of social influence (cf. Cialdini & Ascani, 1976; Condie, Warner, & Gillman, 1976; Ford & Wallace, 1975; Foss, Note 1). Therefore, we may conclude with some confidence that the peculiar nature of blood donation alone does not explain our consistent negative findings.

Erotica and Aggression: The Influence of Sexual Arousal, Positive Affect, and Negative Affect on Aggressive Behavior

Leonard A. White
Purdue University

Male college students were first either angered or not angered by a confederate of the experimenter and were then ostensibly given an opportunity to aggress against the confederate by means of electric shock. Prior to aggressing, subjects were shown one of four sets of stimuli chosen to effect a factorial variation in the intensity of positive sexual arousal (high, low) and negative affect (high, low) elicited by exposure to such material. In addition, one group of angered subjects (no-exposure control) was included who did not view any of the four sets of stimuli prior to being given an opportunity to aggress. Results indicated that exposure to affectively positive erotic stimuli significantly reduced retaliatory behavior by angered males to a level below that exhibited by subjects exposed to neutral stimuli and by those in the no-exposure control group. In contrast, relative to baseline controls, subjects' exposure to erotic stimuli that were reported to be disgusting and unpleasant slightly enhanced subsequent aggressive behavior. A number of possible mechanisms (e.g., attentional shifts, incompatible responses, cognitive labeling) are discussed in relation to these results.

During recent years, it has become apparent that exposure to erotic stimuli may have a variety of effects on subsequent aggressive behavior. In past studies, exposure to sexual imagery has been found at times to decrease attacks against others (Baron, 1974a, 1974b; Baron & Bell, 1977), at other times to increase subsequent aggression (Zillmann, 1971), and at still other times to have seemingly little effect on such behavior. Experimental investigations (e.g., Baron & Bell, 1977) aimed at delineating more precisely the types of erotic material that inhibit or facilitate subsequent aggression have implicated the sexual arousal potential of such stimuli. Specifically, mildly arousing stimuli have been found to decrease subsequent aggression, whereas exposure to more highly arousing sexual imagery tends to facilitate such behavior. In addition, a close examination of past research reveals that affective responses to erotic imagery may also need to be taken into account.

Affective Response to Erotic Stimuli and Aggression

Some suggestion as to the way affective responses may relate to aggression is provided by the results of a recent study by Baron (in press). In the study by Baron, angered females showed increases in aggression following exposure to explicit erotic scenes, which had been found in a previous study (Baron & Bell, 1977) involving males to inhibit such behavior. To reconcile these seemingly discrepant findings, Baron pointed out that females reported finding these depictions of explicit sexual activity to be disgusting and unpleasant, whereas for males, sexual imagery

The author would like to express appreciation to Donn Byrne, Robert A. Baron, Carl Castore, Elizabeth Capaldi, Jeffrey D. Fisher, and William A. Fisher for their valuable comments and assistance in this study. Thanks also go to Donald Amoroso, Kathy Kelley, and the Institute for Sex Research, Bloomington, Indiana, for their assistance in obtaining the experimental stimuli. Finally, the assistance of the Social Science Data Center at the University of Connecticut is gratefully acknowledged.

was regarded as positively exciting and pleasant. These contrasting affective responses, in turn, were hypothesized to have led to different levels of aggression by modifying subjects' attributions concerning the source of their arousal (cf. Baron, 1977; Rule & Nesdale, 1976). Specifically, for females, increments in sexual arousal that were regarded as unpleasant may have been more readily interpreted as anger and consequently increased subsequent aggression. Alternatively, it was suggested that males, who responded with greater positive affect, may have been willing to label their arousal more positively (e.g., as due to the sexual stimuli, rather than as anger), with the result that subsequent retaliatory behavior was reduced.

At first glance, it may appear to follow directly from the studies described above that exposure to erotic materials that are labeled and experienced as unpleasant and disgusting will enhance subsequent aggression, whereas exposure to more positively valenced sexual stimuli effectively inhibits such behavior. Upon closer examination, however, it is apparent that the results described above must be regarded as tentative and clearly demand further experimental scrutiny. For example, in the studies by Baron (Baron, in press; Baron & Bell, 1977) outlined above, while depictions of explicit sexual activity may have evoked contrasting affective responses by males and females, these feelings were not measured directly in the study involving males, but inferred from subjects' comments during debriefing. In addition, since baseline control groups have not been included in past studies of erotica and aggression, it is possible that what has been interpreted as an aggression-inhibiting effect of positively valenced sexual imagery was actually due to an aggression-facilitating effect of more boring and less arousing control stimuli (cf. Zillmann & Sapolsky, 1977). In addition, no evidence is available concerning the impact of more negatively valenced sexual imagery on subsequent aggression by males. Thus, the present study was designed to provide data relevant to answering some of the questions surrounding the past research described above, through an examination of the influence of erotica-produced affect and arousal responses on aggression.

Dimensions of Affective Response

One final concern surrounding the preparation of specific sets of stimuli involved the measurement of affective responses to erotica and their relationship to sexual arousal. Toward this end, the present study incorporated the results of recent work (Byrne, Fisher, Lamberth, & Mitchell, 1974) that delineates these relationships more precisely. The results of this research indicate that sexual arousal and affective responses to erotica may be conceptualized as varying along two orthogonal dimensions—one dimension that I will refer to as *positive sexual arousal,* composed of subjective sexual arousal and positive affective responses related to sexual arousal, and an orthogonal dimension of *negative affect,* characterized by responses of disgust, nausea, and guilt. Within this two-dimensional framework, four distinct patterns of response to erotic stimuli can be identified: Exposure to erotic imagery may lead to increases in sexual arousal that are labeled and experienced as pleasant and entertaining (*positive response*), evoke a combination of positive affect and negative feelings (*ambivalent response*), lead primarily to negative affect (*negative response*), or elicit feelings of relative indifference (*neutral response*).

Experimental Design and Hypotheses

Procedures in the present investigation followed closely those used by Baron (e.g., Baron & Bell, 1977) in past research relating exposure to erotica and aggression. Male college students were either angered or not angered by a confederate and were then provided with an opportunity to aggress against the confederate by means of electric shock. Prior to aggressing, participants were exposed to one of four sets of stimuli chosen to effect a factorial variation in the intensity of positive sexual arousal (high, low) and negative affect (high, low) associated with an erotic stimulus. Each set of stimuli was chosen to elicit one of the four categories of response to

rotic imagery outlined above—positive, negtive, ambivalent, and neutral.

Based on the discussion above, an interction was anticipated such that aggressive esponding would be (a) inhibited by expoure to erotic stimuli that evoked primarily ositive affect (positive response), (b) enanced by exposure to arousing erotic imagery nat evoked a combination of positive and egative affect (ambivalent response), and c) neither reduced nor facilitated by exosure to neutral stimuli or erotic imagery hat led primarily to heightened negative eelings. Simple increases in negative affect esulting from exposure to sexual stimuli negative response) were not expected to ncrease subsequent aggression, since the failitation of aggression by erotica presumably equires heightened levels of sexual arousal e.g., Baron & Bell, 1977). Although this redicted pattern of results was expected to e more clearly evident for angered males relative to nonangered), this prediction must e regarded with caution, since exposure to rotic stimuli has been found (e.g., Baron & Bell, 1977) to alter aggression by nonangered ersons.

Finally, to determine if the anticipated eduction in aggression by exposure to erotic magery that evokes primarily positive affect nay actually represent an aggression-facilitating effect of neutral control stimuli, a group of provoked subjects was included who lid not view any of the four sets of stimuli rior to being given an opportunity to aggress.

Pilot Study

Method

Prior to the main experiment, a pilot study was conducted to determine if the chosen sets of stimuli were suitable for inducing a factorial variation in positive sexual arousal and negative affect.

Thematic Content of the Experimental Stimuli

Each of the four sets of experimental stimuli was composed of 10 color slides that depicted the following themes: (a) positive response—mutual genital fondling, sexual intercourse, and mildly explicit fellatio; (b) ambivalent response—moderately explicit mutual oral–genital contact, fellatio, and cunnilingus; (c) negative response—same-sex masturbation and highly explicit cunnilingus; (d) neutral response—clothed and partially clothed males and females standing alone or mutually involved in what seemed to be a nonsexual activity.

Subjects and Procedure

After providing informed consent, 48 male undergraduates were randomly assigned to view one of the four sets of stimuli until a total of 12 subjects had rated each set. Following presentation of the stimuli, each participant completed a Feelings Scale (Byrne et al., 1974) that required a rating of sexual arousal and self-ratings of affect along 10 dimensions: disgusted, entertained, anxious, bored, angry, nauseated, depressed, guilty, excited, and disappointed with oneself. Males then responded to items pertaining to sexual-physiological reactions (Schmidt & Sigusch, 1970) and to six semantic-differential scales.

Results and Discussion

As an initial step in the analysis, responses to the Feelings Scale (for all four sets of stimuli combined) were factor analyzed and orthogonally rotated using a varimax criterion (Kaiser, 1958). In line with expectations based on past research (e.g., Byrne et al., 1974), two orthogonal dimensions of response were found. The first factor, accounting for 35% of the variance, was labeled as "positive sexual arousal" and consisted of the rating of sexual arousal and four positive affective responses related to sexual arousal (excited, anxious, entertained, and not bored).[1] The second factor, accounting for 30% of the variance, was labeled "negative affect" and consisted of responses to the items angry, disgusted, nauseated, disappointed with oneself, depressed, and guilty.

Subsequent analyses sought to determine if the chosen sets of stimuli produced the intended differentiations in response along these two dimensions. Multivariate analysis of variance applied to responses along these two dimensions yielded the intended differentiations, showing only a main effect of positive sexual arousal, multivariate $F(5, 40) =$

[1] Anxiety as a positive response would appear to denote feelings of positive anticipation and excitement that preceded the onset of each stimulus.

Table 1
Mean Affect and Arousal Responses to Experimental Stimuli in the Pilot Study

Condition	Positive sexual arousal		Negative affect	
	Sexual arousal	Positive affect related to sexual arousal	Disgust	Negative affect (with disgust)
High sexual arousal/high negative affect (ambivalent response)	4.17_a	4.18_a	3.17_a	2.39_a
High sexual arousal/low negative affect (positive response)	4.17_a	4.10_a	1.25_b	1.23_b
Low sexual arousal/high negative affect (negative response)	1.25_b	1.95_b	4.33_a	3.37_a
Low sexual arousal/low negative affect (neutral response)	1.67_b	2.12_b	1.00_b	1.18_b

Note. $n = 12$ within each cell. A higher number (on a 7-point scale) indicates more intense affect and arousal responses. Within each dependent measure, means that do not share a common subscript differ significantly at the .05 level by Duncan's multiple-range test.

10.02, $p < .001$, and a main effect of negative affect, multivariate $F(6, 39) = 12.09$, $p < .001$.[2] As summarized in Table 1, males exposed to erotic imagery chosen to elicit high (as opposed to low) negative affect reported much greater disgust ($p < .0001$), as well as more intense anger, nausea, guilt (for each item, $p < .001$), and self-disappointment ($p < .02$). In addition, and as intended, sets of stimuli chosen to elicit high positive sexual excitement (as opposed to low) were reported to be more sexually arousing, more exciting, more entertaining, less boring, and more anxiety provoking (for each item, $p < .001$).

Corroborating the above findings, males more frequently reported either a partial or full erection, $F(1, 40) = 23.33$, $p < .001$, and greater physical excitement, $F(1, 40) = 27.97$, $p < .001$, in response to those stimuli chosen to elicit high (as opposed to low) levels of positive sexual arousal. In addition, males reported feeling more negative, unpleasant, uncomfortable, sad, and bad (for each item, $p < .005$) following exposure to those stimuli selected to elicit more intense negative affect.

Taken collectively, the findings described above indicate that the four sets of stimuli can be used effectively to create the intended factorial variation in positive sexual arousal and negative affect.[3]

Main Experiment

Method

Subjects

Participants were 95 males who were at least 18 years of age and were attending a major midwestern university. Fifty-one males who had not taken a course in psychology and had not participated in a previous psychology experiment were recruited from classes in introductory communication. Each student received extra credit in his communication class in exchange for his participation. Since only a limited number of students were available via communication classes, an additional 44 males were recruited by means of advertisements in the student news-

[2] All of the multivariate analyses of variance reported in the pilot study and in the main experiment used Pillai's trace criterion, described by Morrison (1967), as the multivariate test statistic.

[3] As a part of the pilot study, subjects' dispositional affective orientation to sexuality was measured by the Sexual Opinion Survey (White, Fisher, Byrne, & Kingma, Note 1). Validation studies have indicated that subjects who score high on this scale (erotophiles) report more intense sexual arousal, greater positive affect, and less negative affect following exposure to erotica, relative to those subjects who score low (erotophobes). Analysis of responses to the Feelings Scale, which included this measure, revealed that the desired factorial variation in positive sexual arousal and negative affect was evident for both erotophiles and erotophobes. Thus, the experimental manipulations appear to be generally effective across individual differences in affective orientation to sexuality.

paper, in which it was stipulated that volunteers should not have taken a course in psychology and that each volunteer would be paid $2.00.[4]

Design and Apparatus

The main experiment was arranged as a $2 \times 2 \times 2$ between-subjects factorial with factors corresponding to two levels of provocation (angry, not angry) and the intended characteristics of the experimental stimuli, positive sexual arousal (high, low) and negative affect (high, low). One group of angered subjects was also included who were not shown any of the four sets of stimuli prior to the opportunity to aggress. Participants were randomly assigned to each of the nine cells with the stipulation that each group ($n = 10$) contain an approximately equal number of paid volunteers and students from communication classes.

The apparatus consisted of a modified Buss (1961) "aggression machine," lists of 40%–60% Glaze association nonsense syllables, and a bogus intercom system. Ten push-button switches numbered from 1 to 10 were arranged in a row across the front of the aggression machine and were ostensibly to be used to deliver shocks of varying intensity to another person. A Lafayette stop clock (Model 54015) was used to record shock duration.

Procedure

The procedure followed closely that described by Baron and Bell (1977) and as a result will only be briefly outlined here.

After obtaining informed consent, the male experimenter escorted both the subject and the confederate to the experimental room, where it was explained that they would work on an impression-formation task. For purposes of this task, both individuals began by writing a brief summary of the central aspects of their own personalities, then examined each other's descriptions, and finally exchanged their mutual impressions of each other.

Anger manipulation. As in previous studies (Baron, 1978; Baron & Bell, 1977), the confederate's rating of the subject was prepared in advance by the experimenter in order to manipulate the subject's anger toward the confederate. In the *angry* condition, the personality rating ostensibly provided by the confederate was very unfavorable and quite insulting. In the *nonangry* condition, the rating by the confederate was more favorable. To enhance the anger manipulation still further, the confederate described himself as being "rather intolerant of others" in the angry condition and, in a more neutral manner, as "an average sort of guy" in the nonangry condition.

Aggression phase. Following the impression-formation task, the subject and the confederate were seated in a second room where the aggression machine was located. It was then explained that the second portion of the experiment would now begin, and was to be concerned with the effects of exposure to unpleasant stimuli on physiological responses. During this part of the experiment, one person would serve as a *responder* and receive a series of electric shocks delivered by the *stimulator.* Through the use of a rigged drawing, the confederate was designated to be the responder and the subject to be the stimulator.

The responder was then taken to an adjacent room, where the experimenter attached two sets of electrodes to the confederate's hand and wrist in full view of the subject. The electrodes were ostensibly to be used to record the responder's physiological responses and for the delivery of finger shock. The recording electrodes, in turn, were attached to a polygraph, which the subject could see.

The experimenter then proceeded to explain to the subject his role as the stimulator. It was initially made clear that the responder would be trying to memorize a list of eight paired-associate trigrams, which the stimulator would administer to him using the intercom located next to the aggression machine. Presumably, the use of this memory task would allow the experimenter to obtain more accurate evidence concerning the effects of unpleasant stimuli on physiological responses by effectively distracting the responder, and thereby preventing him from trying to "get ready" for each shock. Following these remarks, the experimenter informed the subject that at certain times a red signal light would be illuminated, at which time he (the stimulator) was to deliver an electric shock to the responder by depressing one of the 10 buttons on the aggression machine. It was made clear that the occurrence of the red signal light was random and was in no way related to the responder's performance on the paired-associates task. In order to familiarize the subject with the levels of shock supposedly to be used, sample shocks from buttons 4 and 5 were administered to the stimulator.

Presentation of the experimental stimuli. Following the sample shocks, the subject was told that there would be a short delay before continuing the experiment, in order to insure that the responder's physiological responses had returned to baseline levels. To fill this waiting time, the experimenter indicated that he had been asking subjects to rate some slides that he was planning to use in a future study. All subjects agreed to view and rate the stimuli, and were then shown one of the four sets

---

[4] Responses from five subjects were not included in the data analysis. Four subjects (two angered and two nonangered) were suspicious of some aspect of the experimental manipulations, and one subject was dismissed who failed to follow instructions properly.

In addition, since the results of a preliminary analysis revealed that the type of incentive used to recruit subjects (i.e., paid vs. course credit) had no significant effect on either the intensity or duration of shocks delivered to the confederate, this classification variable will not be mentioned further.

of 10 color slides described in the pilot study. Each slide was automatically projected once onto a screen for 20 seconds. Two seconds elapsed between the offset of one slide and the onset of the next slide. Following presentation of the stimuli, subjects completed a Feelings Scale (cf. Pilot Study).

While the subject was viewing the stimuli and reporting his reactions, the experimenter waited in the next room, where the confederate was located. Two minutes after the slides were presented, the experimenter informed the subject that the responder was ready. The experimental trials were then initiated. The red shock signal was given 20 times during the session. Both shock intensity and shock duration were recorded on each of the 20 trials.

No-exposure control. Ten angered subjects did not view or rate any of the four sets of stimuli. Individuals in this group were told that the experimenter would use the available free time while the responder's responses were stabilizing to adjust the polygraph, and no mention was made of the slides. The experimenter then returned to the room where the confederate was seated, while the subject sat and waited. Three minutes later the experimenter returned, informed the subject that the responder was ready, and then initiated the experimental trials.

Postexperimental questionnaire and debriefing. Following the last shock trial, subjects completed a questionnaire on which they reported (on 10-point scales) if they thought that there was a certain number of high (and low) intensity shocks that they were supposed to give (definitely yes/definitely not); if they tried to deliver shock as they thought others might have done (definitely yes/definitely not); their level of anger toward the confederate (angry/not angry); their feelings toward the confederate (comfortable/uncomfortable, pleasant/unpleasant, positive/negative); and how anxious they were for the experiment to end (not at all anxious/very anxious). A brief verbal suspicion check was then administered, followed by an extensive debriefing.

Results

Affect and Arousal Responses to the Experimental Stimuli

Statistical procedures used to determine if the experimental stimuli produced the intended differentiations in affect and arousal response followed closely those used for this purpose in the pilot study. As in the pilot study, subjects' ratings of themselves as sexually aroused, not bored, entertained, excited, and anxious, loaded on a common factor, and were combined to form a single multivariate F value, which was used to assess the effectiveness of the manipulation of positive sexual arousal. Analysis yielded the required differences, showing only a main effect of positive sexual arousal, multivariate $F(5, 68) = 9.37$, $p < .001$. Participants reported being more sexually aroused, entertained, excited, less bored (all $p < .001$), and more anxious ($p < .02$) following exposure to sets of stimuli chosen to elicit high (as opposed to low) positive arousal: $M = 3.44$ for high sexual arousal, and $M = 1.85$ for low sexual arousal, on a 7-point scale.

Next, subjects' responses to items relating to disgust, anger, nausea, guilt, depression, and self-disappointment were combined to form a single multivariate F value that was used to determine the effectiveness of the manipulation of negative affect. Responses to these six items each shared high loadings on a single factor, as in the pilot study. Analysis revealed only the desired main effect of negative affect, multivariate $F(6, 67) = 6.41$, $p < .001$. Responses to those stimuli chosen to elicit high (rather than low) negative affect were most strongly differentiated with respect to feelings of disgust ($p < .0001$): $M = 3.90$ for high negative affect, and $M = 1.70$ for low negative affect, on a 7-point scale. In addition, subjects reported greater nausea ($p < .002$), depression ($p < .002$), guilt ($p < .01$), anger ($p < .02$), and self-disappointment ($p < .10$) in response to those stimuli chosen to evoke more intense negative feelings.

Taken as a whole, the results presented above, in conjunction with those of the pilot study, strongly indicate that the experimental manipulations were effective.

Aggressive Behavior

Subjects' shock intensity, shock duration, and a transformed Shock Intensity × Shock Duration score (composite measure) were combined to form a single multivariate F value, which was interpreted as an index of aggressive behavior toward the confederate.[5] Table 2 presents the mean level of aggression (for all three measures) in each of the nine

[5] The transformed Shock Intensity × Shock Duration measure has been used in past studies of human aggression (e.g., Baron, 1978; Baron & Bell, 1977). This composite measure was calculated from subjects' shock intensity and shock duration scores using a simple transformation, $X = (x + 1)^{\frac{1}{4}} + (x)^{\frac{1}{4}}$, where x equals the product of shock intensity and shock duration.

Table 2
Aggression as a Function of Exposure to Erotic Stimuli and Prior Provocation

Condition	Shock intensity		Shock duration (sec)		Composite measure	
	Nonangry	Angry	Nonangry	Angry	Nonangry	Angry
High sexual arousal/ high negative affect (ambivalent response)	4.66_{ab}	5.29_{ac}	$.46_{bc}$	$.72_{a}$	3.23_{bc}	4.06_{a}
High sexual arousal/ low negative affect (positive response)	3.95_{bc}	3.86_{b}	$.36_{b}$	$.44_{bc}$	2.68_{b}	2.84_{bc}
Low sexual arousal/ high negative affect (negative response)	3.22_{b}	5.28_{ac}	$.29_{b}$	$.64_{ac}$	2.37_{b}	3.86_{ac}
Low sexual arousal/ low negative affect (neutral response)	4.43_{ab}	5.57_{a}	$.36_{b}$	$.51_{ab}$	2.84_{bc}	3.61_{ac}
No-exposure control[a]		5.11		.44		3.26

Note. $n = 10$ within each cell. A higher number indicates more intense shock (on a 10-point scale) and shock of longer duration (range = .01 to 2.68 sec). For each dependent measure within the eight basic experimental groups, means that do not share a common subscript differ significantly at the .05 level by Duncan's multiple-range test.

[a] For shock intensity, high sexual arousal/low negative affect versus no-exposure control, $F(1, 27) = 2.26$, $p < .05$ (one-tailed), by Dunnett's test.

experimental groups. Multivariate analysis of variance applied to aggression scores yielded a significant main effect of provocation, multivariate $F(3, 70) = 4.67$, $p < .005$, and a main effect due to negative affect, multivariate $F(3, 70) = 3.02$, $p < .05$, which was further qualified by a significant interaction between negative affect and positive sexual arousal, multivariate $F(3, 70) = 2.82$, $p < .05$.

As an initial step in further probing these significant findings, the main effect due to provocation was examined more closely. Univariate tests revealed that individuals who received a negative evaluation from the confederate (relative to nonangered subjects) evidenced stronger aggression on each of the three measures of such behavior: $F(1, 72) = 8.24$, $p < .01$, for shock intensity; $F(1, 72) = 11.61$, $p < .001$, for shock duration; and $F(1, 72) = 14.37$, $p < .001$, for the composite measure. Thus, it appears that the manipulation of anger was generally effective.

Turning next to the effect of exposure to the various types of erotic stimuli on aggression, univariate tests revealed that the main effect due to negative affect failed to attain significance on any of the three dependent measures of aggression: Fs$(1, 72) = .21$, 3.10, and 3.24, all ps $> .05$, for shock intensity, shock duration, and the composite measure, respectively. A closer examination of the significant multivariate interaction between positive sexual arousal and negative affect, however, yielded a parallel univariate effect for shock intensity, $F(1, 72) = 6.86$, $p < .05$, and the composite measure, $F(1, 72) = 5.51$, $p < .05$, but not for shock duration, $F(1, 72) = 1.71$, $p > .20$. Simple effects tests were then used to probe differences among the four group means comprising these significant univariate interactions. Analysis revealed that aggressive behavior toward the confederate was reduced by exposure to erotic stimuli that evoked primarily positive responses, relative to the effect of exposure to neutral material; $F(1, 72) = 4.93$, $p < .05$, for shock intensity: and relative to ambivalent stimuli; $F(1, 72) = 4.74$, $p < .05$, for shock intensity; and $F(1, 72) = 8.60$, $p < .01$, for the composite measure.

Because further inspection of the means presented in Table 2 suggested that a more

complex pattern of results might underlie the interactive effects presented above, the means of all eight groups were compared (for all three measures) using Duncan's multiple range tests. As can be seen in Table 2, the results of these comparisons revealed that exposure to erotic stimuli that evoked primarily positive affect reduced retaliatory behavior by angered individuals ($p < .05$), but had only weak or negligible effects on aggressive behavior by nonangry persons. Thus, the effect of exposure to the various types of erotic stimuli on subsequent aggressive behavior toward the confederate was most clearly evident for angered males.

Finally, Dunnett's test (Dunnett, 1955) was used to compare each of the four group means within the angry condition against the no-exposure control. The results of this analysis indicated that the intensity of aggressive behavior was inhibited, $F(1, 27) = 2.26$, $p < .05$ (one-tailed test), by exposure to erotic stimuli that led primarily to increases in positive affect. No further comparisons involving the no-exposure control attained significance.

In summary, aggressive behavior toward the confederate was inhibited by exposure to sexually arousing erotic stimuli that evoked primarily positive affect and slightly enhanced by increases in sexual arousal that were responded to with ambivalence.

Postexperimental Questionnaire

Analysis of responses to the postexperimental questionnaire indicated that males who received a negative evaluation from the confederate (as opposed to a neutral one) rated themselves as more angry, $F(1, 72) = 93.17$, $p < .001$; reported being more negative, $F(1, 72) = 32.91$, $p < .001$, uncomfortable, $F(1, 72) = 104.16$, $p < .001$, and unpleasant, $F(1, 72) = 98.19$, $p < .001$; and found their experimental participation to be a less enjoyable experience, $F(1, 72) = 5.91$, $p < .05$. These findings amplify the results described above showing greater aggression by angered males than by nonangry individuals.

Further examination of responses to the postexperimental inventory revealed that participants reportedly felt there was not a correct number of high intensity ($M = 7.15$) or low intensity ($M = 7.21$) shocks that they were supposed to administer to the confederate and reported no obvious intention ($M = 5.71$) to deliver shock in a manner that mimicked the behavior of other participants. Taken as a whole, subjects' mean responses to these items and the failure to find any significant effects for these items due to the independent variables, suggest that the experimental manipulations did not operate simply to evoke an expectation that one pattern of shock was more correct or desirable than another.

Discussion

It appears that exposure to sexually arousing erotic stimuli may sometimes inhibit aggression, and at other times slightly increase such behavior, depending on how exposure to such material makes one feel. In the present study, there was a slight tendency for aggressive behavior to be enhanced by exposure to arousing erotic stimuli that were reported to be disgusting and unpleasant. In contrast with this group, subjects' exposure to sexual imagery reported to be entertaining and positively exciting decreased retaliatory behavior by angered individuals to a level that fell slightly below that of subjects who were never provoked. Further comparison with a baseline control group strongly suggested that exposure to such erotica acted to inhibit aggressive behavior by angry males.

The inhibition of motivated aggression by exposure to positively arousing erotic stimuli observed in the present study may be viewed as corroborating and extending earlier findings (e.g., Baron, 1974a, 1974b; Baron & Bell, 1977; Zillmann & Sapolsky, 1977). Moreover, since only those stimuli which were labeled and experienced as entertaining and exciting led to reductions in retaliatory behavior, it appears that subjects' affective response to such material is a critical factor leading to the inhibition of aggression by erotica.

Alternative Explanations for the Major Findings

Attentional shift. The pattern of results described above may be viewed as generally

failing to support the hypothesis (e.g., Donnerstein, Donnerstein, & Evans, 1975) that exposure to erotic stimuli inhibits aggressive behavior by shifting subjects' attention away from the source of their anger. Based on the arguments presented by Donnerstein et al., it would seem reasonable to expect that exposure to virtually any type of mildly arousing erotic stimuli would be more distracting than sexually arousing and, therefore, would be effective in reducing subsequent aggression. In the present study, however, exposure to seemingly attention absorbing erotic imagery that led to heightened negative affect not only failed to reduce aggression but tended slightly to enhance subsequent aggressive behavior.

Cognitive labeling. One explanation for the results of the present study may be that subjects' contrasting affective responses to arousing erotic imagery led to different levels of aggression by modifying the type of label males applied to any arousal they experienced (Baron, 1977; in press). This interpretation is in keeping with other work (e.g., Geen, Rakosky, & Pigg, 1972; Zillmann & Bryant, 1974) suggesting that whether or not a given source of arousal will act to facilitate or to inhibit subsequent aggression depends on a person's cognitions regarding the source of his or her arousal. Thus, in the present study, following exposure to erotic stimuli that evoked primarily positive responses, males may have been more inclined to label any arousal they experienced in a positive manner (e.g., as sexual excitement or entertainment, rather than as anger), with the result that subsequent retaliatory behavior was reduced. In contrast, following exposure to sexual material that was reported to be unpleasant and disgusting, subjects may have been more willing to interpret any arousal they experienced as anger (rather than resulting from exposure to the erotic stimuli), with the result that aggressive behavior toward the confederate was slightly facilitated, or at least was not inhibited.

The cognitive interpretation presented above assumes that the facilitation of aggression by erotica requires an increase in arousal deriving from exposure to such stimuli and the adoption of a cognitive label appropriate to the expression of aggression (cf. Zillmann & Sapolsky, 1977). In line with this view, simple increases in negative affect resulting from exposure to erotica (negative response) were not found to enhance subsequent aggression in the present study. Continuing this line of reasoning, it is less clear, however, why exposure to reportedly ambivalent material that led to increases in both sexual arousal and negative affect failed to increase subsequent aggressive behavior more significantly. While a number of reasons may be offered to explain this result (e.g., dissipation of negative affect after rating the stimuli), it seems reasonable to suggest that the ambivalent erotic imagery used in the present study simply failed to produce a sufficient degree of sexual arousal (cf. Baron & Bell, 1977). As such, exposure to this set of stimuli may not have generated a sufficiently intense excitatory reaction (i.e., arousal response) whose residue could identify subsequent aggressive behavior (cf. Zillmann, 1971). In support of this interpretation, a closer examination of the present results revealed that angered individuals who reported the highest levels of sexual arousal following exposure to ambivalent stimuli were subsequently found to be the most aggressive: $t(8) = 3.20$, $p < .02$, for shock intensity. In general, however, subjects reported only moderate levels of sexual excitement following exposure to such material ($M = 3.25$, on a 7-point scale) and did not exhibit heightened aggressive attacks against the confederate.

Incompatible responses. Although ambivalent erotic depictions may not have been sufficiently arousing to enhance subsequent aggression, exposure to affectively positive and arousing erotic stimuli was found to inhibit aggression as was predicted. As discussed above, while exposure to such erotica may have effectively reduced aggressive behavior by affording subjects more positive cognitive labels, other, though not necessarily incompatible, explanations are also possible. In particular, positive responses of pleasure, entertainment, and excitement deriving from exposure to sexual stimuli may be hedonically incompatible with feelings of anger and/or the performance of aggressive acts and con-

sequently may inhibit such behavior directly (e.g., Baron, 1974a, 1974b, 1976, 1978; Zillmann & Sapolsky, 1977). That is, once an angry individual becomes immersed in pleasant and entertaining erotic stimuli, it may be difficult to maintain heightened feelings of annoyance or to engage in intense retaliatory behavior. Following the implications of this analysis, it may be that exposure to virtually any pleasant stimulus (e.g., art, scenery) is capable of reducing aggressive attacks by angry individuals. In line with this interpretation, exposure to enjoyable and entertaining cartoons has been found (Baron, 1978; Baron & Ball, 1974) to reduce aggressive behavior by angry persons.

Conclusion

In summary, the present study serves to extend previous research by demonstrating that the effect of exposure to erotic stimuli on subsequent aggression depends, to an important extent, on the type of affective response elicited by exposure to such stimuli.[6] One useful direction for extending the results of the present study and related research, would appear to be to explore further the efficacy of training individuals who have difficulty controlling their anger to emit pleasant images and other incompatible behaviors in response to provocation, as a means of inhibiting anger and reducing the intensity of retaliatory behavior (cf. Baron, 1977; Novaco, 1977; Smith, 1973).

[6] Out of convenience, male subjects and male confederates were used in the present study, which leaves open the question of whether exposure to the various types of erotic stimuli used in the present study would have similar effects on aggressive behavior toward males and females and/or by females toward these target persons. Although empirical research that examines the combinations of aggressors and victims described above may be required to answer these questions definitively for specific types of stimuli, a number of studies are available that may provide at least a partial answer to these concerns. With respect to the sex of the victim, exposure to erotic material has been found (Donnerstein & Barrett, 1978; Jaffe, Malamuth, Feingold, & Feshbach, 1974) to have similar effects on aggressive behavior toward males and females. Further, it has been argued (Baron, in press) that exposure to sexual imagery that evokes similar patterns of affect and arousal responses in males and females will lead to similar levels of subsequent aggression. Thus, on the basis of the evidence available, it may be tentatively assumed that the conclusions of the present study would apply independently of the sex of the aggressor or the sex of the victim. It should be emphasized that the specific characteristics of those stimuli (e.g., thematic content) which evoke positive, negative, ambivalent, and neutral responses may differ greatly for males and females (e.g., Schmidt & Sigusch, 1970).

This study examined speculations by Dawes, McTavish, and Shaklee concerning the extent to which persons use their own responses in mixed-motive situations as a basis for predicting the behavior of others. Female subjects played a one-trial Prisoner's Dilemma game and predicted the responses of their partner and a person in another dyad. As predicted, subjects, irrespective of the particular choice they had made, tended to attribute their own response to others. In many subjects, this attribution appeared to be self-justifying, in that it was specific to the subjects' partner. However, it was even more frequently the case that subjects attributed their own response to both partner and nonpartner (i.e., a false consensus), although they also tended to be more confident about their prediction of their partner's choice.

Dawes, McTavish, and Shaklee (1977) recently speculated that behavior in some mixed-motive situations might not be a consequence of an attribution about the other(s), but, rather, that the reverse relationship might be operating—that is, the attribution about the other's behavior is a consequence of the subject's own behavior. Dawes et al. used a multiperson one-trial dilemma to examine the validity of their position. They compared the attributions to others that were made by participants in a commons dilemma to the attributions that were made by observers who did not participate in the situation but merely predicted the behavior of those who did. They expected that participants would be more variable in their attributions than would observers, given that the former should base their judgments of others on their own behavior. Their findings did support this behavior-to-attribution hypothesis.

Unfortunately, the methodology that Dawes et al. employed did not permit the examination of more specific components of their argument. For example, they speculated that the attributions of persons are influenced by their own actions, irrespective of whether they compete or cooperate. While Dawes et al.'s results suggest that this was the case in their study, their design and analysis did not permit separate examination of the data of the subjects who cooperated and of those who competed. Moreover, prior studies that have examined this hypothesis with encounters of short duration (e.g., Kanouse & Wiest, 1967; Terhune, 1968) have yielded somewhat inconsistent findings, although, on the whole, they support the notion that there is a great deal of correspondence between a subject's choice and the behavior he or she attributes to others.

Dawes et al. (1977) also suggested—but did not examine—the notion that one or both of two mechanisms might account for the hypothesized tendency in subjects in mixed-motive situations to base their judgments about others on their own behaviors. They suggested that subjects might engage in this attributional process in order to justify their responses; subjects who compete might feel the need to justify what could be considered ex-

ploitative and antisocial behavior, and subjects who cooperate might attribute a tendency toward similar behavior to others in order to "avoid feeling duped." In addition, they suggested that subjects might use their own behavior as a guide for guessing "what everybody does." This latter explanation has been termed the "false consensus" phenomenon (see Ross, Green, & House, 1977).

It should be noted that Dawes et al. employed the concept of self-justification somewhat narrowly. Ross et al. (1977), in their discussion of false consensus judgments, suggested that such behavior could be based on a number of underlying processes, including the need to justify oneself. Clearly, if self-justification is a salient motive, it is most efficiently expressed by attributing one's own behavior only to one's partner. But, in a larger sense, this narrow attribution might not be sufficient, perhaps because one needs to believe that one's partner (who often is a stranger) is just like everyone else, or perhaps because there is greater comfort in thinking that one is not atypical in general. On the other hand, other explanations for the false consensus phenomenon also are plausible—for example, that one uses his or her own behavior as the best evidence (perhaps as the only evidence) of what people in general do. In any event, it seemed of interest to attempt to examine the extent to which persons in short-duration mixed-motive situations appear to use their predictions of others to self-justify in the narrow sense suggested by Dawes et al. (1977) or to make more general predictions about the behavior of others, for whatever reason.

Thus, the present study examined the behavior and predictions of subjects in a one-trial dilemma to explore some of the issues proposed but left unresolved by Dawes et al. First, we examined the extent to which both persons who competed and persons who cooperated attributed their own responses to other participants. Second, we used a procedure that permitted differentiation between the false consensus and (narrow) self-justification hypotheses. In the present study, all subjects served as both participants and observers. Thus, they responded in a Prisoner's Dilemma and made predictions about the responses of both their partner and a person with whom they were not paired. This within-subjects procedure permitted examination of both the self-justification and false consensus explanations. To the extent that self-justification is a valid explanation, we would expect that subjects would attribute to their partner a response similiar to their own, but their response would not be related to their prediction about the person with whom they were not paired. On the other hand, to the extent that false consensus is a relevant phenomenon, we would expect that subjects would be likely to attribute responses that were similar to their own to both their own partner and the individual with whom they were not paired.

Method

Subjects

One hundred seventy-two female students from introductory psychology classes at Michigan State University volunteered to participate in the research for extra course credit. In addition, as explained below, they also received up to 80¢ each, depending upon the decision that they and their partners made when playing a one-trial Prisoner's Dilemma (PD) game.

Design

In addition to making a "cooperative" or "competitive" choice in the PD game, subjects also made predictions about their partner's (P) choice and the choice of another person (O) with whom they were not paired. The order in which they made these decisions was varied such that half the subjects made their own choice first, whereas the remainder first made a prediction about the decision of one of the other people. Also, the order of the predictions was varied such that half the subjects predicted their partner's choice first, whereas the other half predicted the nonpartner's choice first. This procedure generated a design whose dimensions were 2 (subjects' choice: cooperate or compete) × 2 (order of subjects' choice: before or after their first prediction) × 2 (order of predictions: about P first or about O first). The latter two factors were included primarily for reasons of experimental control. In actuality, we were primarily interested in (a) the subjects' own choice and (b) the extent to which they attributed the same choice to P and/or O.

Procedure

Subjects were examined in groups of four. When the four subjects in a session had assembled, each was given 30¢ and was paired at random with a male experimenter. One of the experimenters shuffled

Table 1
Outcome Values (in cents) in Prisoner's Dilemma Game

Person A's choice	Person B's choice	
	Cooperate	Compete
Cooperate	25, 25	−25, 50
Compete	50, −25	−10, −10

Note. The first value in each cell is the outcome to Person A.

a deck of four cards (numbered 1, 2, 3, and 4) and dealt one face down to each subject. Then, each experimenter escorted the subject assigned to him to one of four cubicles. From this point on, subjects had no further contact with each other.

Once in the cubicle, the experimenter seated the subject at a small table and presented her with a "typical" 2 × 2 PD matrix. (Table 1 presents the values that were contained in the matrix.) The experimenter explained in detail the nature of the one-trial PD game—there are two players, each has two choices, and so on. At the end of his explanation, which was a script that he had memorized, the experimenter made sure that the subject understood the nature of the game by soliciting questions and reiterating points about which the subject appeared uncertain. The experimenter then informed the subject that the four of them had been divided at random into two pairs and that she had been paired with the person who had drawn "Card Number *X*" (where *X* was a number on one of the cards that had been dealt to the other subjects).

At this point, depending upon the condition to which she had been randomly assigned, the subject was asked (a) to make a choice of PD alternatives—with the understanding that her choice, coupled with that of her partner, actually determined payment to both—or (b) to predict her partner's PD choice, or (c) to predict the PD choice of one of the persons in the other pair. In addition, whenever a subject made a prediction about her partner's or the other person's choice, she was asked immediately afterwards to indicate on a scale of 50 to 100 how confident she was in her prediction. She was told to mark a 50 (indicating a "50–50 guess") if she was merely guessing, a 100 if she was completely confident, or an appropriate number in between to indicate an intermediate degree of confidence. Depending on the nature of the first task, the subject then was asked either to make her own choice and the remaining prediction (and confidence rating) or to make the two predictions (and confidence ratings) in the order dictated by the experimental design.

It should be noted that the subject was not informed that she was to make a series of decisions; that is, she was told about the second task only after she had completed the first, and about the third task only after she had completed the second. It also should be noted that the subject made her judgments in private. The experimenter did not observe her while she was making her decision or her predictions and confidence ratings. In each instance, she was told to fold the card on which she had marked her response(s) before returning it to the experimenter.

When the subject had completed the three tasks, the experimenter excused himself for a moment to consult with the experimenter who had been assigned to her partner. Together they determined the outcome of the one-trial PD game for the pair. Each then returned to his respective subject and adjusted her payment accordingly. Every subject was debriefed, sworn to secrecy, and thanked for her participation. A subject was allowed to leave in such a way that she did not come into contact with the other participants in her session.

Results

The subjects' own PD choice and their predictions about the choices of P and O were examined via chi-square analyses. Similarly, their confidence ratings were examined through analysis of variance (ANOVA). Preliminary analyses were performed to explore the possibility that the order in which subjects performed the three tasks influenced their responses. Then, the data were cast and analyzed in a manner that most directly addressed Dawes et al.'s (1977) speculations.

Examination of Possible Order Effects

Three chi-square tests were calculated to explore the possibility that the four combinations of order of own choice and order of predictions about others' choices influenced the subjects' responses in the PD game, their predictions about their partners' choices, or their predictions about the choice of one person in the other dyad. None of the obtained chi-squares reached significance, χ^2s(3) = 1.03, 1.08, 4.88, respectively, ps > .20. Likewise, a preliminary ANOVA indicated that subjects' relative confidence in a prediction was not affected by order of PD decision, $F(1, 157) = .12$, $p > .70$; order of predictions, $F(1, 157) = .70$, $p > .40$; or their interaction, $F(1, 157) = 0$, $p > .99$.[1] Thus, order of responses was

[1] Note that 7 subjects had missing data, in that they did not give one or both confidence ratings and/or experimenters failed to record their order conditions. Thus, the total sample size for these data was 165.

disregarded in subsequent analyses. It is likely that response orders had little effect, because subjects probably rehearsed their own choice even before they were explicitly told that they were to make one.

Tests of Dawes et al.'s Speculations

As noted above, Dawes et al. (1977) speculated that subjects predict that others will act in a PD situation as the subjects themselves did, irrespective of the specific choice that the subjects made (i.e., irrespective of whether they competed or cooperated). In addition, they also speculated that the tendency to attribute one's own behavior to others might be due to one or both of two mechanisms, self-justification and false consensus. The data and analyses presented below bear directly on these speculations.

Predictions of subjects who cooperated or competed. Table 2 presents the proportions of the 73 subjects who chose cooperatively and the 99 subjects who chose competitively who attributed similar or dissimilar responses to their partner and to the person in the other dyad.[2] These data provide strong support for Dawes et al.'s (1977) speculation, since there was little difference in the frequencies with which persons who cooperated and persons who competed attributed their response to their partner, $\chi^2(1) = .39$, or to the other person, $\chi^2(1) = .92$. In addition, there was a strong tendency for subjects to attribute the same response as their own to their partner, $\chi^2(1) = 38.82$, $p < .001$, and, to a somewhat lesser extent, to the other person, $\chi^2(1) = 6.44$, $p < .025$.

Table 2
Proportions of Competitive and Cooperative Subjects Who Predicted That Others Would Make the Same or a Different Response as Their Own

Subject's response	Predicted response: Same as own	Predicted response: Different from own
Prediction about partner		
Competition	.72	.28
Cooperation	.76	.24
Total sample	.74	.26
Prediction about person in other dyad		
Competition	.63	.37
Cooperation	.56	.44
Total sample	.60	.40

Table 3
Proportions of Subjects Who Made Similar or Dissimilar Predictions About Their Partner's and the Other's Responses

Prediction about other's response	Prediction about partner's response: Same as subject	Prediction about partner's response: Different from subject
Same as subject	.44	.16
Different from subject	.30	.10

Examination of the self-justification and false consensus predictions. Dawes et al. (1977) speculated that the attribution of one's own behavior to one's partner probably was based on one or both of two mechanisms: an attempt to justify one's decision and the tendency to use one's own behavior as the basis for generalizing about everyone's behavior. To examine the validity of these predictions, data were organized by tabulating the number of subjects who attributed their own behavior to both their partner and the other person, the number who attributed such behavior only to their partner, the number who attributed their own response only to the other, and the number who attributed their response to neither party. (Since there was no difference in the attributions of similarity by competitors and cooperators, the data were collapsed across this variable.) Table 3 presents these data (in the form of proportions).

A chi-square test of this array (McNemar's test for correlated proportions; see Hays,

[2] Note that data are presented in the tables in the form of proportions, to make the comparison of the data of subjects who cooperated and of those who competed more straightforward, given that competitive responses were made somewhat more frequently, $\chi^2(1) = 3.70$, $p < .075$. Of course, in every case the chi-square analyses were performed on the raw frequencies.

Table 4
Mean Confidence Ratings of Subject's Predictions of Partner's and Other's Responses

Prediction about partner	Confidence in prediction of	
	Partner	Other
Same response as subject (124)	69.38	63.93
Different response from subject (44)	62.92	64.94

Note. Scores could range from 50 (indicating no confidence) to 100 (indicating complete confidence). Numbers in parentheses indicate cell frequencies.

1963, p. 602) yielded a significant value, $\chi^2(1) = 7.29$, $p < .01$. Thus, there was a greater tendency to attribute similar behavior to one's partner than to a nonpartner. Although this finding provides support for the self-justification hypothesis, the false consensus hypothesis also appears to be supported to some extent as well, since the frequency with which subjects attributed their own behavior to both P and O was significantly greater than the frequency with which subjects attributed such behavior only to their partner, $\chi^2(1) = 4.50$, $p < .05$.

Analysis of Confidence Scores

Recall that subjects were asked to indicate how confident they were in each of their predictions. These data were analyzed via a 2 (prediction about partner) × 2 (prediction about other) × 2 (target of confidence rating: partner/other) ANOVA with repeated measures on the third factor.[3] This analysis yielded one significant effect: the Prediction About Partner × Target of Confidence Rating interaction, $F(1, 164) = 6.76$, $p < .01$. Table 4 presents the relevant cell means. Subsequent simple effects analyses (Winer, 1971, pp. 347–351) of these data revealed that subjects who predicted that their partners would behave as they did expressed more confidence in their prediction about their partner than in their prediction about the person in the other dyad, $F(1, 164) = 7.15$, $p < .01$, irrespective of whether they predicted that the nonpartner would respond similarly to, or differently from, them. However, subjects who predicted that their partner would choose differently from them were no more confident in their prediction about their partner than in their prediction about the other person, $F(1, 164) = .89$. Thus, these findings indicated that even those subjects who predicted that both P and O would choose as they did were more confident in their predictions about P than about O.

Discussion

The results provide strong support for Dawes et al.'s (1977) speculation that people predict that others will behave as they themselves did in one-trial PD situations, irrespective of whether their behavior was cooperative or competitive. Moreover, this attributional phenomenon appears to be due to both a need to justify one's response and a tendency to think of one's own behavior as typical of everyone. As noted above, however, Dawes et al. employed the concept of self-justification somewhat narrowly. It could be, in fact, that those subjects who attributed their own response to both partner and other did so in an attempt to justify their own behavior (e.g., "I'm just doing what my partner and everyone else in this situation would do"). The finding that these subjects had more confidence in their prediction of their partner's behavior than they had in their prediction of the other's behavior lends indirect support for this interpretation. This result suggests that subjects might have possessed a greater need to believe that their partner would choose as they did than to believe that someone whose behavior was irrelevant to them would do so.

Two related findings of the present research appear to merit special attention, since they suggest that, for whatever reasons, the judgments of subjects were not entirely rational. As noted above, subjects were more likely to predict that their partner would behave as they did than they were to attribute

[3] Preliminary analyses revealed no main effects or interactions for subjects' own choice (compete or cooperate). Thus, the data were collapsed on this factor. It should also be noted that 4 subjects failed to provide confidence scores for their predictions. This analysis, therefore, was based on data from 168 subjects.

this choice to the nonpartner; also, they had greater confidence in the attribution of a similar choice when they made this prediction about their partner. These results occurred in spite of the fact that the procedure used precluded the possibility that subjects could objectively differentiate their partner from the nonpartner. Recall that in a given session, all four subjects were led into separate cubicles, and they could know only that their partner and the other person about whom they made a prediction were two of the three people in the other cubicles. There was no way that they could identify these two people specifically. Thus, subjects had no objective basis for making differential predictions or confidence ratings; yet they tended to do so. These findings suggest that there is some within-subject process (or processes)—a need to justify one's own behavior, a need to feel in control (Langer, 1975), and so forth—that produce(s) the illusion in subjects that the two targets of their predictions are identifiably different.

The systematic study of the relationship between people's behaviors and their predictions of others' behaviors in mixed-motive situations began with Kelley and Stahelski's (1970) examination of the "triangle" hypothesis. They proposed that people who compete in mixed-motive situations do so because they have a biased perception that other people are competitive; on the other hand, cooperators are less likely to stereotype in this fashion, and thus, their behavior is influenced by the actual behavior of the other person. Dawes et al. (1977) proposed their explanation as a contrasting position to Kelley and Stahelski's triangle hypothesis. They concluded that their findings—and most likely they would conclude that our findings as well—tend to disconfirm Kelley and Stahelski's explanation. In fairness, however, it should be noted that this conclusion is somewhat extreme. While there is ample evidence (e.g., the present study; Dawes et al., 1977; Kanouse & Wiest, 1967; Miller & Holmes, 1975) that the triangle hypothesis is not valid in all mixed-motive situations, Kelley and Stahelski (1970) themselves noted that biased perceptions should affect responses only under limited circumstances. And there is evidence (e.g., their own study; Miller & Holmes, 1975) that the triangle hypothesis is valid in substance under the appropriate conditions (i.e., mixed-motive situations of extended duration in which contingent cooperation is both rational and congruent with social norms; see, for example, Luce & Raiffa, 1964, p. 101).

Thus, taken as a whole, the present and previous studies provide evidence that no single explanation can account for the link between behavior and attributions in all mixed-motive situations. Instead, the processes that underlie this linkage appear reasonably complex. Therefore, attempts to demonstrate the general utility of one perspective over another seem to be a less fruitful pursuit than are attempts to understand the conditions under which the different processes proposed by these perspectives operate.

Information, Choice, and Reactions to Stress: A Field Experiment in a Blood Bank With Laboratory Analogue

Richard T. Mills
University of Southern California

David S. Krantz
Uniformed Services University of the Health Sciences

Two experiments examined the effects of various operations of personal control on reactions to stress. The first study incorporated two features into the blood-drawing procedure at a blood bank: providing donors with accurate information and allowing donors to choose the arm to be used. Measurement of nurses' actions to prevent donors from fainting and self-reports of discomfort revealed that the combination of choice and information was somewhat effective in reducing distress. However, providing either information or choice alone was more effective. In a second laboratory study using a cold pressor stimulus as stressor, subjects given a choice (the option to terminate the aversive stimulus and choice of hand used) showed a reduction of aftereffects on a measure of attention to detail. Subjects given information but not choice also showed this reduction. Combining information and choice was no different from either treatment alone. Taken together, the results of both studies indicate that moderate levels of choice and information are optimal for coping with stress. An explanation was suggested based on a contextually determined relationship among choice, information, and perceived control.

Laboratory and field studies have shown that negative effects of threatening stimuli are frequently lessened when subjects believe that they can escape or avoid them (e.g., Glass & Singer, 1972; Seligman, 1975) or when subjects are provided with information about the threatening event (e.g., Johnson, 1973; Staub & Kellet, 1972). In addition, providing subjects with options or choices may also affect behavioral and physiological stress reactions (e.g., Corah & Boffa, 1970; Langer & Rodin, 1976; Stotland & Blumenthal, 1964). These operations have been conceptualized as forms of personal control because they presumably allow subjects to alter or affect outcomes. Recent investigations have explored the applications of personal control to naturalistic health care situations that are inherently stressful. In this regard, information, participation, and choice have been implicated as important variables that may influence outcomes in both health treatment settings and the institutional environments (Krantz & Schulz, in press; Langer & Rodin, 1976; Leventhal & Everhart, 1978).

Situational Context and Control Interventions

A recent review, however, concluded that various operations of personal control are related to stress in a complex fashion (Averill, 1973). The particular situational context and

Experiment 1 was conducted as part of the first author's second year project at the University of Southern California under the direction of the second author. During this time, Richard Mills was also employed as research associate in nursing research at City of Hope National Medical Center. In the public domain

the meaning of the control response to the individual determines whether it will be effective in reducing stress. This conclusion is supported by studies demonstrating an interaction among some operations of personal control. For example, Corah and Boffa (1970) manipulated the ability to escape (terminate) or not escape a loud noise. Half of the subjects were also given instructions that heightened their sense of choice about what to do, and the remainder were not given a choice. Results indicated that ability to escape was stress reducing. Choice reduced stress for the no-escape subjects, but was *not* effective (and even increased rated discomfort) for subjects given an escape response. Other research indicates that under certain conditions, making responses available to subjects or providing information may actually be stress inducing (Averill & Rosenn, 1972; Epstein, 1973). One conclusion that can be drawn from this research is that the situational context affects the outcome of interventions. Therefore, to determine the specific effects of real-life operations of control, it is necessary to conduct studies in naturally occurring settings.

The first study in this article examines the effects of operations of personal control on donor stress reactions to giving blood (phlebotomy). Blood donors were selected as the target population because giving blood is a real-life stress situation that lends itself easily to experimental interventions. We manipulated information and choice because both these variables are of theoretical interest in medical settings.

Effects of Information and Choice

Information has been conceptualized as a form of cognitive control because it often results in the interpretation of an aversive event so that the threat is lessened. Research suggests that accurate information about sensations is effective in reducing distress (cf. Johnson, 1973), presumably because it increases ability to prepare for and validate experience with aversive events. Sensory information has been shown to reduce distress associated with noxious medical examinations and unpleasant procedures (Johnson & Leventhal, 1974; Fuller, Endress, & Johnson, Note 1) as well as to facilitate recovery from surgery (Johnson, Rice, Fuller, & Endress, Note 2).

Participation and choice often lead to an increase in perceived control. Choice is seen as a form of control because it may provide subjects with the perception (correct or not) that they can have an effect on outcomes.

Both choice and participation have also been described as effective means of facilitating favorable health outcomes and reducing distress associated with various medical procedures (Cromwell, Butterfield, Brayfield, & Curry, 1977; Krantz & Schulz, in press; Taylor & Levin, 1976). Langer and Rodin (1976), in a study of institutionalized elderly people, found that providing elderly residents with the freedom to make choices about daily matters and enhancing their sense of responsibility for rather routine events resulted in heightened activity, happiness, and well-being. Moreover, a long-term follow-up found that the choice and responsibility interventions had sustained positive effects on measures of health and mortality (Rodin & Langer, 1977).

Rationale and Hypotheses

Although recent discussions of behavioral approaches to health care encourage the active involvement of clients in their own treatment (e.g., Cromwell et al., 1977; Taylor & Levin, 1976), there has been relatively little systematic investigation of the effects of various types of patient control. In a blood-bank setting, allowing donors to choose the arm to be used was a means of increasing donor involvement that could easily be incorporated into the ongoing procedure. Providing information about sensations and procedures is another means of enhancing control that could be easily incorporated into the procedure. Since little is known about how information and choice might operate together, research combining these operations can provide insight into possible positive or negative effects of providing for patient control over some aspects of treatment.

Experiment 1

The present study is designed to evaluate the effectiveness of information and choice in a real-life setting. Accordingly, we manipulated both information about the blood-drawing procedures and participation in the process by allowing donors to choose the arm to be used. Assuming that enhancing personal control would reduce distress in blood donors, it was expected that information and choice manipulations would each reduce distress involved in the phlebotomy procedure. We also expected that the combination of information and choice would reduce distress and perhaps be more effective than either treatment alone.

Method

Overview

Forty blood donors were assigned to one of four conditions in a 2×2 design. The two manipulated factors included information (high/low) and choice (high/low). High-information subjects heard taped communications describing the upcoming procedures and discussing physical and psychological sensations donors frequently experience. Low-information subjects heard a Red Cross documentary tape of comparable length revealing little about procedures. High-choice subjects were allowed to select the arm to be used for phlebotomy, whereas low-choice subjects were merely instructed that the nondominant arm would be used. After the manipulations, a nurse drew blood according to the standard American Red Cross procedure. Donor stress reactions were indexed by observing the necessary health maintenance actions taken by a trained nurse and also through self-reports of discomfort, pain, and anxiety experienced at several points in the procedure. The Stroop color-word test, a response-competition performance measure, was administered during the donor recovery period.

Subjects and Recruitment

Subjects were 40 first-time donors who passed American Red Cross screening at a local blood bank in Southern California. Twelve additional donors were approached, but they declined to participate in the study. There were 19 males and 21 females, ranging in age from 17 to 50 years, with a mean age of 26.7. Subjects were randomly assigned to conditions with the qualification that groups contain an approximately equal number of males and females.

Procedure

Subjects were tested individually. After initial screening, each subject was escorted to the testing area by a nurse. The potential subject was informed by the first experimenter of the general nature of the study, which was "to find ways to make donors more comfortable while giving blood." After agreeing to participate and signing a consent form, subjects completed brief self-report scales including premanipulation ratings of pain, discomfort, and anxiety on "visual analogue" scales (Ohnhaus & Adler, 1975). These scales contained printed instructions and were anchored with the words *none* at one end and *severe* at the other. Subjects were then assigned randomly to one of four conditions that were factorial combinations of the two experimental treatments. The manipulation for each subject was introduced by an appropriate tape-recorded message.

Information manipulation. Half of the subjects (high information) listened to a 2-minute high-information tape that described the step-by-step procedures involved in donating blood and that also discussed some of the physiological and psychological sensations commonly experienced by donors. Excerpts of the message used are as follows:

> There are three steps involved in donating blood: the preparation of the arm, the donation itself, and a short rest period afterwards. . . . We will clean your arm with soap and an antiseptic, then one of the nurses will place a blood pressure cuff on your arm, inflate it, select the largest vein from the area that has been cleaned, and insert a needle. Some people feel a slight sting initially, due to the medication that's in the needle. Once the needle is in place, blood will flow into the collection bag. After about 10 minutes the nurse will remove the cuff and the needle. If you should feel a slight numbness or tingling in your arm while the blood is being drawn, it will go away once the cuff is removed. Then you will relax. Should you feel a little faint, there's no reason to be concerned—you need a few moments to adjust.

The remaining subjects (low information) heard a taped message of comparable length that discussed the Red Crosss blood donor program but revealed little about the upcoming procedures. That message, containing statistical and very general documentary information, was excerpted from a recent report on donor recruitment (Sherer, 1976).

Choice manipulation. The tape continued with an additional 2-minute message introducing the appropriate choice manipulation. Half of the subjects (high choice) heard a message designed to heighten their feelings of active participation in the procedure by telling them that they would be allowed to choose the arm from which blood would be drawn. The message was designed to lead the donors to use a standard arm (nondominant arm), although they were actually given the opportunity to choose

whichever arm they preferred (18 of 20 subjects chose the nondominant arm). Excerpts of the message used are as follows:

> It is now time for you to choose the arm that we will use. . . . Other donating centers have their donors use the nondominant arm. That's so that if there's any soreness due to the needle afterwards, it will be on the nondominant arm and will not interfere with their normal routine. But remember, this study is interested in your role in the blood-drawing process. Therefore, regardless of what other centers have decided, here, the choice about your arm is completely up to you. Which arm do you choose? [Subjects then chose the arm that they preferred to use for the phlebotomy.]

The remaining half of the subjects (low choice) were merely instructed that the nondominant arm would be used in the blood-drawing procedure. The justification for use of this arm was to "prevent soreness from interfering with normal routine." Subjects were given no choice in selection of the arm.

Dependent Measures

Following the taped messages, subjects were escorted to the blood-drawing area where an experienced nurse from the blood center (who was blind to the subject's experimental condition) drew blood according to the standard Red Cross procedure.

Measurement of nursing interventions. During the blood-drawing procedure, the nurse performing the phlebotomy closely observed the subjects for signs of faintness and distress. The nurse was instructed to intervene as she judged necessary and to respond to her assessment of the intensity of donor reactions in a standard, graded fashion. The type and severity of health maintenance action between nurse and donor could therefore be used as a measure of donor distress. The severity of nursing interventions was coded by a second observer who was also blind to the subject's experimental condition. Earlier pilot work as well as data collected during the study revealed that nurse–donor interactions could be standardized in a way that reflected intensity of action required by donors. Nurse interventions were coded on a 4-point scale as follows: 1 = brief verbal communication to insure that the donor was not having an adverse reaction; 2 = extended verbal communication to reassure the donor (and check on his/her status); 3 = physical contact (touch); and 4 = the use of cold towels and/or ammonia capsules to revive the patient. Use of this procedure made it possible to systematically measure nursing interventions and at the same time to provide necessary care to donors. In addition, both nurse and observer independently responded yes or no to whether they had observed adverse physical reactions in donors during the phlebotomy. Physical reactions were defined as overt signs of perspiration, tension, dizziness, or fainting.

Postsession self-ratings and performance measures. After the blood drawing was concluded, the second observer administered scales containing instructions that asked subjects to retrospectively rate the degree of pain, anxiety, and discomfort they experienced during the time blood was being drawn. Subjects also rated their postsession reactions, indicating how they felt after the procedures were over. Next, according to usual Red Cross procedures to facilitate recovery, subjects were given juice and a snack. After these refreshments were offered, subjects were given the Stroop color-word test. This timed response-competition task, given in three parts, has been used as a measure of behavioral aftereffects of stress (Glass & Singer, 1972). Manipulation checks and debriefing concluded the procedure.

Results [1]

Checks on Experimental Manipulations

The manipulations were effective in inducing both differential perceptions of choice and differential perceptions of information received from the taped communications. An item on the postexperimental questionnaire asked subjects to indicate where they received the most information about the blood-drawing procedure. Seventy-nine percent of subjects in the high-information conditions rated the taped message as their primary source of information, whereas 37% of those in the low-information conditions did the same, $\chi^2(1) = 5.29$, $p < .03$. Low-information subjects indicated that other sources had provided them with the most information (e.g., companions, nursing staff).

Subjects responded to the question, "To what extent did you have a choice in selecting which arm would be used for blood drawing?" on a 5-point scale. A 2 (choice) × 2 (information) analysis of variance of this item revealed the expected main effect for choice, $F(1, 34) = 110.90$, $p < .001$. There was also a main effect for information, $F(1, 34) = 4.16$, $p < .05$, with high-information groups rating more perceived choice. There were no other significant effects. Examination of the means for each condition indicated that the high-information–high-choice and low-information–high-choice groups

[1] Data were recoverable for only 38 subjects on manipulation checks and for 39 subjects on self-rating measures of distress.

Table 1
Number of Subjects Requiring Each Type of Nurse Intervention and Mean Intervention Score

Condition	Severity of intervention				
	None	Verbal status check	Touch	Cold towels	*M* intervention score[a]
Low information–low choice	1	2	2	5	1.9
Low information–high choice	7	2	0	1	1.3
High information–low choice	8	1	0	1	1.2
High information–high choice	4	2	1	3	1.6

Note. There were 10 subjects in each condition.
[a] This score was computed by dichotomizing nurse actions as none versus intervention (verbal, touch, or towels). Higher scores on this scale reflect greater severity.

rated the most choice ($M = 4.9$ and 4.7, respectively) with ratings for high-information–low-choice ($M = 2.0$) and low-information–low-choice groups ($M = 1.0$) significantly lower ($p < .05$ by Newman–Keuls test). High-information–low-choice subjects also apparently perceived somewhat more choice than their low-information–low-choice counterparts ($p < .05$).

Nurse Interventions During Blood Drawing

The principal measure of donor distress during the phlebotomy procedure consisted of observer ratings of nurse interventions coded on a 4-point scale of intensity (no adverse reaction to the application of cold towels). In addition, both the nurse and second observer recorded whether an adverse reaction (overt weakness, dizziness, or faintness) was present or absent. Evidence for the reliability of nurse intervention intensity as a measure of distress was provided by the fact that everyone (10 subjects) who received cold towels was rated by the nurse as having had a reaction. Across the range of interventions there was 80% agreement between independent reports of reactions made by the nurse and the second observer.

It was hypothesized that donors who were singly given information or choice would show reduced stress responses and that the combination of these factors would be even more effective in reducing stress. The data for the 4-point measure of nurse interventions are presented in Table 1. These data were not normally distributed and, strictly speaking, were not appropriate for analysis of variance. To overcome this distributional problem, the dependent measure was first dichotomized as no intervention versus intervention (verbal communication, touch, or towels) and then subjected to a 2 (choice) × 2 (information) analysis of variance.[2] This analysis revealed no significant main effects ($p > .15$). Instead, there was a significant interaction between choice and information treatments, $F(1, 36) = 12.86$, $p < .002$. This effect indicated that although the high-information–high-choice ($M = 1.6$) condition reduced the severity of interventions relative to the low-information–low-choice condition ($M = 1.9$, $p < .05$, by Newman-Keuls test), both conditions required significantly greater nurse interventions ($p < .05$) than either the high-information–low-choice ($M = 1.2$) or low-information–high-choice groups ($M = 1.3$). In short, these results indicated that although combining information and choice was effective in reducing stress reactions, information or choice given alone was more effective. This conclusion is further supported by a multivariate analysis of variance conducted on the cluster of measures of distress during blood drawing (namely, nurse intervention intensity and rated discomfort, pain, and anxiety dur-

[2] Analysis of variance on the original 4-point nurse intervention data in Table 1 revealed the identical pattern of results as did post hoc contrasts.

Table 2
Mean Self-Ratings of Three Sections of Experiment

Experimental condition	Self-rating measure of distress	Section of experiment: Pre-manipulation	Blood drawing[a]	Postsession[a]
Low information–low choice[b]	Pain	1.2	4.3	1.4
	Discomfort	2.5	3.8	2.1
	Anxiety	4.6	4.2	1.6
Low information–high choice[b]	Pain	1.3	3.4	1.2
	Discomfort	1.9	1.5	1.1
	Anxiety	3.8	2.5	1.1
High information–low choice[c]	Pain	1.2	1.8	1.6
	Discomfort	1.9	1.1	1.7
	Anxiety	3.3	3.8	2.6
High information–high choice[b]	Pain	1.7	3.5	2.5
	Discomfort	2.8	4.0	2.3
	Anxiety	5.1	4.2	2.1

Note. These ratings were taken on visual scales ranging from 1 = none to 14 = severe.
[a] Means for this measure are adjusted for premanipulation score.
[b] $n = 10$.
[c] $n = 9$.

ing the procedure). The analysis revealed a significant interaction between information and choice treatments, $F(4, 32) = 4.55$, $p < .01$, and no main effects. Relevant univariate effects for these variables are presented elsewhere in the results section.

Self-Ratings

Subjects were asked to rate degree of perceived discomfort, pain, and anxiety on 14-point scales for three separate time periods, with high scores indicating greater distress. The first rating was conducted prior to delivery of the experimental manipulations. The next two ratings were taken after blood drawing. It should be noted at the outset that subjects tended to rate the measures of distress toward the low end of the scale. On premeasures of discomfort, pain, and anxiety, there were no initial group differences prior to receiving the manipulations. This was confirmed by separate 2 (high–low choice) × 2 (high–low information) analyses of variance on each premeasure of the three rated measures of distress that revealed no significant effects (all $ps > .20$).

In the postsession following blood drawing, two ratings were made. Subjects retrospectively rated discomfort, pain, and anxiety felt *during* phlebotomy and then rated their present (postphlebotomy) perceptions on each measure of distress scale. To determine how the manipulations affected self-ratings, repeated measures analyses of covariance[3] were conducted. For each choice of either discomfort, pain, or anxiety, respective premanipulation ratings served as the covariate and the two postmanipulation measures as the within-subject term. Adjusted means for these ratings are presented in Table 2.

Covariance analysis for discomfort revealed a significant trials effect, $F(1, 35) = 12.69$, $p < .002$, indicating greater discomfort during blood drawing than for the postmeasure. Simple effects were not significant; however, there was a reliable interaction between choice and information treatments, $F(1, 34) = 4.35$, $p < .05$. The interaction parallels the finding for nurse interventions and indicates that

[3] Although there were no significant between-conditions effects on premeasures, covariance analyses were used for postmanipulation ratings to correct for small initial differences. A repeated-measures analysis of variance on these measures of distress revealed the same but somewhat stronger pattern of results.

both the low-information–low-choice and high-information–high-choice groups rated more discomfort than low-information–high-choice and high-information–low-choice subjects. Moreover, a significant interaction between choice, information, and trials, $F(1, 35) = 4.60$, $p < .04$, reinforced the fact that between-conditions differences were greatest for rated discomfort during blood drawing. This conclusion was confirmed by separate 2×2 analyses conducted on ratings of each trial. For rated discomfort during blood drawing, the Choice × Information interaction was significant ($p < .03$). For discomfort in postsession, this effect was weaker ($p < .09$).

Repeated measures covariance analysis of pain ratings once again revealed a trial effect, $F(1, 35) = 11.81$, $p < .003$. The only other significant effect was an interaction between information treatments and trials, $F(1, 35) = 4.44$, $p < .05$. The nature of this interaction was revealed by separate 2×2 analyses for each trial. For ratings of pain during blood drawing, there were no significant effects ($ps > .17$), whereas for self-reported pain in postsession, a main effect for information treatments emerged, $F(1, 35) = 4.45$, $p < .05$. This effect indicated higher postsession pain ratings for the high-information groups. Newman-Keuls tests revealed that this effect was largely due to the high-information–high-choice group rating more pain than all the other groups in postsession ($p < .05$) and the low-information–high-choice group rating less pain than all the others ($p < .05$).

Finally, repeated measures covariance analysis of anxiety ratings revealed only a significant trials effect, $F(1, 36) = 7.67$, $p < .01$, reflecting a decrease in rated anxiety across trials.

Pearson correlation coefficients were computed between the 4-point nurse intervention measure and self-ratings of experience during blood drawing. Obtained coefficients for the 39 cases were .31 for pain, .30 for discomfort, and .46 for anxiety. These correlations of moderate magnitude were all significant ($ps < .03$). In sum, results for the self-rating data are generally supportive of the results obtained on the behavioral measure of nurse interventions. Single manipulations of information and choice were effective in reducing distress indexed by rated discomfort and, to a weaker extent, by a postmeasure of pain. There was some indication that ratings were highest for the group receiving the combination of information and choice. For rated anxiety, the treatments did not appear to have any differential effect.

Stroop Color-Word Interference Test

Analysis of this measure revealed no significant main effects or interactions.

Discussion

Results of this experiment suggest that information and choice manipulations, administered alone, are effective means of reducing distress during a phlebotomy procedure in a blood-bank setting. However, when these treatments are combined and given together, their effects are not additive. On a measure of nursing interventions, the data indicate that high levels of both information and choice are somewhat less effective than single manipulations of either variable. The pattern of results obtained on self-rating data are more complex, but still support the general conclusion that moderate degrees of personal control appear to be optimal for coping with stress in this setting.

Although relatively few studies have examined the effects of choice in conjunction with other operations of personal control, results of the present study resemble those obtained by Corah and Boffa (1970), who examined the effects of combining choice with the ability to escape aversive stimulation. They found no evidence that these combined treatments were more effective than single manipulations of either variable. In fact, Corah and Boffa found that subjects given both choice and ability to escape aversive noise actually rated the noise as producing as much discomfort as the group receiving neither treatment. This is the same effect for rated discomfort obtained in the present study.

Although much of stress research is characterized by a dissociation among behavioral,

self-report, and physiological measures (cf. Glass & Singer, 1972; Lazarus, 1966), a problematic feature of the present study is a degree of inconsistency among the various self-rating indexes of distress. Although rated discomfort and the postsession measure of pain generally support the conclusion that moderate levels of personal control reduce distress, neither self-rated anxiety nor rated pain during blood drawing were affected by the manipulations in this study. It should be noted that ratings tended to be rather low—indicating little stress. This may have been so because donors chose to give blood and to be subjects. Moreover, rating data were gathered during the postsession after nursing measures were taken to assist donors in coping with the physical distress of giving blood.

Reflecting on the original hypotheses of the study, we sought to determine if two treatments that could be easily incorporated into the ongoing blood-donating procedure would lessen donor distress. The surprising result on the nurse intervention measure indicated that in the high-information–high-choice group, there were actually more severe reactions than in the groups receiving only one manipulation. Fortunately, this condition still resulted in less severe reactions than those in the group given neither information nor choice. In a purely descriptive sense, this finding reinforces Averill's (1973) conclusion that the context and meaning of a "control response" determines whether it will be effective in reducing stress. However, we might speculate briefly about the cognitive mechanisms that could have produced these results. One possibility is that the combination of information and choice manipulations gave donors more of a role in the blood-drawing procedure than they would have preferred. That is, after being informed of the procedures and sensations, donors might rather have had the nurse be responsible for the rest of the procedure. This explanation raises the intriguing possibility that participation or choice might actually result in a decrease in "perceived control" (ability to affect outcomes) if the individual prefers not to have it or believes that it will not be effective (see Houston, 1972). Under those circumstances, increased choice or participation may even heighten stress. Although others have speculated that this possibility may apply to health care outcomes (Freidson, 1975; Rodin & Langer, 1977), this issue has not been extensively researched and deserves further investigation.

Finally, there were no reliable effects on Stroop test performance at the end of the study. An examination of the blood-bank procedure, however, revealed several reasons why group differences in performance on an aftereffects task may not have been observed in that setting. In addition to receiving cold towels and ammonia capsules, subjects with adverse reactions were reassured and reoriented; their stress was reduced. We suspected that the nursing interventions during phlebotomy and refreshments given to donors following the procedure precluded an adequate assessment of aftereffects in that setting. We therefore conducted a partial laboratory replication of the blood donor study to determine if information and choice can prevent aftereffects of exposure to aversive stimulation.

Experiment 2

Research (Glass & Singer, 1972) suggests that a variety of stressors—at least when they are unpredictable and uncontrollable—produce aftereffects that appear relatively soon after stimulation is terminated. Aftereffects have been observed as impairments in performance of a variety of tasks including measures of frustration tolerance and attention to detail. Moreover, Glass and Singer (1972) have shown that if subjects believe they have control over the onset or offset of aversive stimuli, these negative aftereffects of stress arousal are reduced. In several studies, this "perceived control" variable was manipulated by providing subjects with the option of terminating an aversive stimulus.[4] The ex-

[4] Glass and Singer (1972) have conceptualized operations similar to this manipulation as "perceived control," whereas others (e.g., Corah & Boffa, 1970) have termed it *choice*. Although we feel it is reasonable that choice and perceived control do not always vary together, we have evidence that the choice manipulation in Experiment 2 did heighten feelings of control (see Results section).

plicit relationship between providing information about a stressor and behavioral aftereffects has not been investigated previously.

To create a rough analogue to the blood-drawing procedure, a cold pressor stimulus was used in which subjects immersed their hand in ice water. Half of the subjects (high information) received information about the sensations of a cold pressor stimulus (coldness, aching, etc.), whereas the remaining half (low information) received no information. Crosscutting this treatment, half of the subjects (high choice) were allowed to choose the hand to be used and could elect to remove their hand from the cold water if they chose to do so. The remaining subjects (low choice) were not given these options. Dependent measures included performance on an aftereffects task and self-ratings. Based on the results of the previous study, it was predicted that single manipulations of information and choice would be effective in preventing aftereffects on a poststress task. The combined manipulations were not expected to be any more effective than either treatment alone and perhaps somewhat less effective as observed on some measures in the first study.

Method

Subjects

Subjects were 44 undergraduate psychology students at the University of Southern California who received class credit for participation. There were 13 males and 31 females in the sample who were randomly assigned to one of the four experimental conditions.

Procedure

Subjects were tested individually. After being greeted by the experimenter, each subject was seated at a table and was instructed that the purpose of the experiment was to "measure blood pressure under various conditions." During the study subjects were told that they would be required to place their hand in ice water and were given the option to withdraw from the study. (All subjects elected to continue.) Each subject then heard a taped message describing 7-point self-report adjective scales to be used during the study. The tape was stopped to make sure instructions were being understood, and subjects filled out a premeasure of Likert scales measuring their present state of discomfort, pain, and anxiety. The scales were anchored by 1 = none at all, 4 = moderate amount, and 7 = most ever experienced. After the subjects completed these premeasures, the tape was turned on again, and prerecorded messages presented the appropriate experimental manipulations.

Information manipulation. Half of the subjects (high information) listened to the high-information manipulation that described the physiological and psychological sensations commonly experienced by persons who placed their hands in ice water. The manipulation was as follows:

> We would like to let you know what you can anticipate from holding your hand in the ice water. Most people report a coldness, aching, tightness of the skin across the hand. Also, they experience a "pins and needles" sensation and numbness. Such reactions are normal, and after you remove your hand from the water, the reactions will go away.

The remaining half of the subjects (low information) received no information at this point and heard only the subsequent messages.

Choice manipulation. Half of the subjects (high choice) heard instructions that emphasized their ability to determine which hand would be inserted into the water. (Instructions encouraged choice of the nondominant hand.) In addition, although discouraged from doing so, they were told they would be able to withdraw their hand if they chose. Excerpts of the message are as follows:

> The next step is holding your hand in the ice water . . . You can place whichever hand you want into the water . . . the choice of hands is entirely up to you. It is important that you do not exchange hands after you have placed one of them in the water. Secondly, while we would like the subjects to keep their hand in the water for a predetermined length of time, you are free to withdraw your hand at any time you may wish. Now pick the hand you will place in the water. We find that most people pick the hand that they do *not* use for writing so that you can fill out the scales with the free hand. When I tell you, place your hand in the metal bowl, resting your palm flat on the bottom surface. Although a few people who come here don't keep their hand submerged the full time, most do. For the success of the experiment, I prefer you to keep your hand submerged until I tell you remove it, but that's entirely up to you.

The remaining half of the subjects (low choice) were told which hand they would insert into the water and were told not to remove their hand. The message was as follows:

> It is important that *I* control the length of time you keep your hand in the water. For this study to be successful, all the subjects must be exposed to the ice water for the same length of time. So

please keep your hand in the water until I tell you to remove it. Also, we have chosen the hand you will place in water. Place the hand that you do *not* use for writing in the water so that it will be easier for you to fill out the scales. When I tell you, I will want you to place your hand in the metal bowl, resting your palm flat on the bottom surface. Leave your hand there until I tell you to remove it.

At this point all subjects submerged their hand in a flat-bottomed metal pan containing ice water at 5 °C. The tape recorder remained on and after 2 minutes delivered a message instructing subjects to again complete the four self-rating scales. This measure reflected self-reports during exposure to the cold pressor stimulus. After a total of 4 minutes had elapsed from the time of submersion, the tape instructed subjects to remove their hand from the water. At this time the experimenter measured blood pressure with a cuff and administered postmeasures.

Postsession ratings. After subjects removed their hand from the water, they were asked to indicate once more how they had felt when their hand was submerged in the ice water and, finally, to indicate how they felt *at that moment*. As with the premeasure, these ratings were taken on scales measuring discomfort, pain, and anxiety.

Aftereffects task. The final task for the subject was to proofread a simplified version of a 10-page passage used extensively in previous research (e.g., Glass & Singer, 1972; Krantz & Stone, 1978) to measure attention to detail. This passage contained typographical errors, misspellings, and grammatical and punctuation mistakes. Subjects were instructed to proofread the passage, detect the errors, and underline them. Instructions emphasized both accuracy and speed. After instructions were given, the subject was left to work alone for 6 minutes, although nothing was said about time. In accord with previous research using this measure (e.g., Glass & Singer, 1972; Krantz & Stone, 1978) a percentage correct score was computed as a measure of performance. This score consisted of the percentage of correctly located errors in the portion of the passage completed by subjects when asked to stop working. This was a measure of performance accuracy correcting for amount read. "Total amount read" was also analyzed. After the proofreading task, manipulation checks were administered and subjects were debriefed.

Results [5]

Manipulation Checks

Data from postexperimental questions indicated that the manipulations were effective. Subjects were first asked to rate (on a 7-point scale) the degree of choice they had in selecting the hand to be placed in the cold water.

Table 3
Mean Percentage of Correctly Located Errors on Proofreading Task

Information	High choice	Low choice
High	71.2	67.8
Low	74.2	52.3

Note. $n = 11$ subjects per condition. Higher scores reflect better performance.

A 2 (high–low information) × 2 (high–low choice) analysis of variance revealed that high-choice subjects indeed rated more choice, $F(1, 40) = 89.30$, $p < .001$. There were no other significant effects. A similar analysis was conducted on an item asking subjects to rate the degree of choice they felt in determining when their hand would be removed from the water. Once again, only the appropriate main effect for choice emerged, $F(1, 40) = 71.40$, $p < .001$.

To check on the information manipulation, subjects were asked how much information they had received about sensations they would experience from the cold water. Analysis of these 7-point scale ratings revealed only an information main effect, $F(1, 40) = 62.57$, $p < .001$.

Dependent Measures

Aftereffects task. It was predicted that single manipulations of information and choice would prevent behavioral aftereffects of exposure to the experimental stressor. High levels of both information and choice were not expected to produce any additional remedial effect. A two-way analysis of variance was conducted on percentage of errors correctly identified on the proofreading task. Means for this measure are presented in Table 3. There was a significant main effect for choice, $F(1, 40) = 12.52$, $p < .001$, with

[5] Four subjects in the high-choice conditions removed their hand from the ice water before the full 4-minute submersion period. Data both excluding and including these individuals on all dependent measures were analyzed. Results on all measures were virtually identical both ways. Therefore, data for the full complement of 44 subjects are presented.

high-choice subjects ($M = 72.7$) being more accurate than low-choice subjects ($M = 60.1$). In addition, there was an unreliable tendency toward an information main effect ($p < .09$). A significant Choice × Information interaction also was evident, $F(1, 40) = 6.66$, $p < .02$. This interaction indicated that under low-choice conditions, providing information led to improved performance ($p < .05$ by Newman-Keuls test). Under high-choice conditions, providing information made little difference and even depressed performance slightly, though not reliably. Newman-Keuls tests revealed that the low-choice–low-information group was significantly less accurate than the other three groups ($p < .05$). The latter three groups, however, did not differ reliably from one another.

An analysis was also conducted on amount of the proofreading passage read (i.e., number of lines of text) during the 6-minute test period. This 2 × 2 variance analysis revealed only a significant Choice × Information interaction, $F(1, 40) = 4.00$, $p < .052$. This interaction indicated that low-information–high-choice subjects read the most ($M = 52.2$ lines), followed in decreasing order by high-information–low-choice ($M = 48.7$ lines), high-information–high-choice ($M = 43.5$ lines), and low-information–low-choice ($M = 39.8$ lines). These individual group mean differences did not reach reliable levels of significance ($ps > .05$ by Newman-Keuls); however, these data demonstrate that on a measure of performance speed as well as accuracy, the effects of information and choice are not purely additive in preventing aftereffects.

Self-Report Measures

Analyses of variance (2 × 2) were conducted on each premeasure of discomfort, pain, and anxiety. These analyses revealed no initial premanipulation rating differences between groups on any of the measures of distress. Next, to determine if postmanipulation self-reports were affected by the experimental treatments, repeated measures analyses of covariance were conducted on the three subsequent measures of distress. These analyses revealed no significant treatment effects or interactions for any of the measures. On 7-point scales, mean self-ratings during submersion ranged between 4.5 and 5.1 for discomfort, 4.0 and 4.4 for pain, and 3.1 and 3.9 for anxiety. For each measure of distress, however, there was a significant trials effect ($ps < .01$) reflecting heightened aversive experience during the cold pressor test and subsequent relief in postsession. Examination of the means revealed that relative to premeasures, experience during cold pressor was rated with heightened discomfort, pain, and anxiety by subjects in all conditions. In addition, Pearson correlation coefficients were computed between rated experience during the cold pressor test and the aftereffects measure of percentage correct on proofreading. These correlations were uniformly low and nonsignificant, indicating a lack of relationship between these measures.

Other Relevant Data

Analysis of blood pressure measured following the cold pressor test revealed no reliable effects. However, it is worth noting that there was considerable variance in this measure, and the low-information–low-choice and high-information–high-choice groups tended to show somewhat higher systolic and diastolic blood pressures. Additionally, in a postexperimental questionnaire, subjects rated the degree of control they felt over removing their hand from the water An analysis of variance of this item revealed only a choice main effect ($p < .01$), with high-choice subjects rating more control.

Discussion

Results on the behavioral aftereffects of measure of Experiment 2 are generally consistent with our hypotheses and with the results of the first experiment. The information and choice manipulations were effective in preventing performance deficits when each was given alone; combining the treatments added little to subsequent performance. The data on the proofreading measure also reveal that the choice manipulation was more potent than providing subjects with relevant in-

formation in preventing behavioral aftereffects.

The manipulations in Experiment 2 did not affect any of the self-reports of discomfort, pain, or anxiety; and correlations between aftereffects and self-ratings were nonsignificant, as in the Glass and Singer (1972) research. Although related studies (e.g., Glass & Singer, 1972, pp. 47–55; Sherrod, Hage, Halpern, & Moore, 1977) have reported that control manipulations did not affect rated aversiveness, other studies have found a tendency for predictable and controllable stimuli to be rated as less aversive (Corah & Boffa, 1970; Fuller et al., Note 1). We have no ready explanation for these apparent inconsistencies. Further investigation is necessary to clarify the conditions under which self-report measures are or are not affected by manipulations of personal control.

In our discussion of the results of Experiment 1, we speculated that too much patient control might not be desired or expected in a blood bank. In accord with this explanation, we found in the first study that both of the groups receiving only one manipulation experienced reduced stress reactions compared to the high-information–high-choice condition. Results of the cold pressor study (Experiment 2) indicate that groups receiving either combined or single manipulations evidenced reduced stress on an aftereffects task. We attribute this somewhat different pattern of results to characteristics of the respective settings in which the studies were conducted and also to the particular operations used to manipulate choice.

First, subjects in a laboratory study probably do not enter the situation with established expectancies about how much control they will be allowed. Therefore, in contrast to a clinical setting, there is little expectancy violation involved in being given control over a laboratory stressor. Second, the nature of the choice manipulation in the cold pressor study (i.e., the option to terminate the stimulus) made it explicitly associated with "perceived control" (Glass & Singer, 1972). Subjects had every reason to believe that this form of control would be effective in terminating the aversive stimulation, thereby promoting the stress-reducing properties of this treatment. (Note the choice main effect.) This logic argues that choice manipulations will reduce stress to the extent that they are perceived to be effective in regulating aversiveness.

The two studies presented here shed light on some of the complexities of the control–stress relationship. Based on these findings, we can conclude that information and choice can play a useful role in remediating adverse physical reactions to an aversive health-care procedure. Reasonably similar manipulations were shown to affect the magnitude of behavioral aftereffects induced by a laboratory stressor. In both studies, there was little or no gain in effectiveness from combining the treatments. In light of the economic and medical benefits of self-care and the growing application of behavioral science principles to health-care settings (e.g., Krantz & Schulz, in press; Leventhal & Everhart, 1978), it is important to investigate further the effects of personal control in its various operational forms. Moreover, subtle differences between the clinical and laboratory settings suggest that naturalistic study of this problem can be maximally beneficial.

Measuring Causal Attributions for Success and Failure

Timothy W. Elig and Irene Hanson Frieze
University of Pittsburgh

A great deal of research has been generated by the Weiner et al. attribution model of achievement behavior. Although generally supportive of the model, the literature is marred by a lack of concern with the reliability and validity of the measurements used. In this study, causal attributions for a manipulated success–failure event were collected from college students on five different measuring instruments. Results indicated that the open-ended response measure showed poorer interest correlation validity than did the structured measures. Rating scales showed a better fit to attribution conceptualizations than did the percentage method. Overall, scale measures seem to be the method of choice, although possible uses for open-ended measures of attributions are suggested.

Although a great deal of research based on Weiner et al.'s (1971) model of causal attributions for success and failure events has been published during the 1970s, relatively little attention has been given to the question of how causal attributions should best be measured (Deaux & Farris, Note 1; Smith, Note 2). Although a few articles (e.g., Elig & Frieze, 1975; Frieze, 1976; Weiner, 1974; McHugh, Note 3) have referred to the variety of measures used for assessing attributions, there has been no formal study of the implications of using one attribution measure over another, and researchers have tended to be unsystematic in their selection and use of the common techniques. This article explores the interrelationship of several measures of causal attributions to assess their validity and to make recommendations concerning the selection of instruments to be used in future studies of causal attributions for success and failure events.

As shown in Table 1, there are a number of commonly used techniques for assessing causal attributions: open-ended responses, independent ratings, ipsative ratings, choice of one major cause, and bipolar ratings. Each of these methods has its own advantages and disadvantages in terms of practical considerations.

Most attribution studies use structured ratings rather than open-ended data. An open-ended procedure involves asking subjects to state in their own words why a particular event has occurred. These verbal responses can then be classified by a skilled rater into any of a set of previously defined attributional categories. Such a coding procedure is described more fully by Elig and Frieze (1975). Other systems have been developed by Bar-Tal and Darom (in press) and by Cooper and Burger (Note 4). The necessity for training coders and the time-consuming nature of this type of causal assessment contributes to its rare use in attribution research. However, there are also problems with structured response measures, which confine subjects to a limited set of factors defined in advance by the experimenter as important for the situation. This set may not include the factors of importance for some subjects. Open-

Portions of this article were presented at the meeting of the American Psychological Association in 1978 and served as part of the requirements for a master's degree for the first author.

The authors would like to thank Grace French-Lazovik, Maureen McHugh, Diane Ruble, Eliot R. Smith, and Bernard Weiner for comments on earlier drafts of this article.

Requests for reprints should be sent to Irene Hanson Frieze, Department of Psychology, University of Pittsburgh, Pittsburgh, Pennsylvania 15260.

Methods of Assessing Causes of Success and Failure

Method	Method used by	Example
Unstructured		
Open-ended	Elig & Frieze (1974, 1975) Frieze (1976) McHugh (Note 5)	Why do you think you *succeeded* on this task?
Structured		
1. Independent		
Unipolar ratings	Feather & Simon (1971b, 1972) Valle & Frieze (1976)	Rate the extent to which these factors caused your *success:* 1. If the factor to no extent caused the outcome. 9. If the factor to an extremely high extent caused the outcome. Your high general intelligence _____ How easy this type of task is _____
2. Ipsative		
Percentage assessment	Meyer (1970)	To what extent was your *success* caused by your high general intelligence _____ how easy this type of task is _____
Choice of one cause	Bailey, Helm, & Gladstone (1975)	Which of the following contributed the most to the outcome? Ability Effort
Bipolar ratings	Feather (1969) Feather & Simon (1971a) Weiner, Nierenberg, & Goldstein (1976)	My outcome was mainly due to: Ability–Luck[a]
Paired comparisons	McMahan (1973)	Of each pair, circle which is more responsible for your outcome. Ability, luck Ability, effort

[a] Measured on a 5-point scale.

ended response measures avoid this problem as well as the cuing of subjects toward considering causal possibilities that they may not have spontaneously considered (Frieze, 1976; Smith, Note 2).

Weiner et al. (1971) postulated that individuals attribute the causes of success and failure primarily to four of the causal elements discussed by Heider (1958): ability, effort, task difficulty, and luck. Several studies using structured measures supported the belief that these factors are used by subjects in systematic ways to explain achievement outcomes (e.g., Frieze & Weiner, 1971; Weiner, Heckhausen, Meyer, & Cook, 1972; Weiner & Kukla, 1970). Frieze (1976) employed open-ended questionnaires to ascertain what causes college students naturally used to explain success or failure in two achievement tasks (an exam and an unspecified game). The results indicated that the four causal factors postulated by the Weiner et al. (1971) model were used by subjects for these situations and accounted for the large majority of causal attributions. However, two additional causal factors, mood and other people, were also indicated. Other recent studies (Elig & Frieze, 1975; McHugh, Note 5) that used open-ended questions for a variety of social and achievement situations found still other causal factors that are frequently used to explain success and failure. Among these are personality, interest in the task, and physical appearance. This research supports

the importance of the four causes proposed originally but suggests the importance of other factors not previously considered, especially for dealing with nonacademic situations. These results raise serious questions about studies relying only on the four causal factors of ability, effort, luck, and task difficulty in a structured format.

An additional advantage of open response assessment is that subjects may find open response questions easier and more natural to respond to. However, even though it is hypothesized in this study that subjects will prefer open-ended questions, it is also hypothesized that open-ended questions will be psychometrically inferior to more structured responses. First, the added step of coding the unstructured responses should lead to lower reliability for open-ended questions than for structured measures. Second, structured measures provide a closer approximation to interval or ratio measurement. Third, structured measures allow for degrees of attribution on various dimensions rather than the simple presence–absence or frequency of appearance measures typical for open-ended response coding.

A major distinction between various structured attribution measures is whether they involve ipsative or independent judgments. Ipsative measures are measures in which the score of one attribution must influence the score of other attributions, thus inducing negative correlations. Negative correlations are not forced by measures using independent judgments. With independence of ratings comes ease of analysis, since each attribution can be tested separately. However, independent ratings do not give as direct an assessment of the relative importance of attribution factors as is given by ipsative judgments. This ease of comparison is the major attraction of ipsative measurement.

Among the ipsative measures, the assignment of percentages to various causes is perhaps the best developed. Percentage ratings (e.g., Meyer, 1970) make explicit the basic assumption of interdependent judgments that the causes being rated account for the totality of cause for the outcome and that the total cause of an event can be parceled out to various particular causes. McHugh (Note 3) pointed out that percentage ratings give the clearest indication of the relative importance of various causes (e.g., luck rated relative to other causes seems unimportant).

Another widely used method of causal assessment, the single bipolar scale anchored by ability and luck used by Feather (1969) and Feather and Simon (1971a), does not allow for even the four causal factors identified by Weiner et al. (1971). It measures only two of the possible causes of events. This measure also confounds two dimensions that have been shown to be important for attributions: stability and locus of control (Weiner et al., 1971). However, multiple bipolar scales could be used in such a way as to overcome the particular problems of using a single bipolar scale (Weiner, Nierenberg, & Goldstein, 1976). Weiner et al. (1976) limited comparisons on each scale to a difference within only one dimension (e.g., luck and ability are not on a scale since they differ on both the stability and the location of cause dimensions). Such a limitation solves the theoretical problem of which dimension the causes were judged on as well as easing the practical problem of the very large number of comparisons needed in a paired comparison of many attributions. Within-dimension bipolar scales (Weiner et al., 1976) yield more sensitive measures than paired comparisons used by McMahan (1973), since the range of possible scores is increased by the use of scales.

Among these structured response measures, separate rating scales and percentage measures appeared to be the most interesting measures. These were selected for further study along with an unstructured, open-ended measure.

A few researchers have begun to question the indiscriminate use of the various attribution measures (Deaux & Farris, Note 1; Smith, Note 2). Deaux and Farris analyzed a variety of measures by looking at differentiation across success and failure and at correlations across measures. They found some convergence, but they also found significant difference between what the various scales measure. This study extends their analysis by using a multitrait–multimethod test of the re-

liability of three of the most commonly used measures: open-ended measures, scale ratings, and percentage judgments. In addition, a formal assessment is made about subjects' perceptions of the face validity of the various measures.

Hypotheses

Two specific hypotheses that can be made concerning various attribution measures involve a comparison of the open-ended response measure with the two structured response measures: (a) Convergent and discriminant validities will be lower for the open-ended response measure than for either of the two structured response measures and (b) the face validity to subjects of the open-ended response question will be better than that obtained by either structured response measure. That is, subjects will rank the open-ended measure as better and easier to answer. Another hypothesis is made based on the apparent superiority of the independent scale judgments: (c) The independent ratings will be superior to the percentage ratings in terms of convergent and discriminant validities.

Method

Subjects

The subjects were 252 students in introductory social psychology and personality psychology classes. Students were requested to participate in a study that would serve as a focal point for class discussions of experimental and measurement procedures in psychology. Subjects were free to participate or not as they chose. Two of a total of 254 students elected not to participate because of their dislike of anagrams.

Attribution Measures

Three types of attribution measures were used. The measures were worded separately for success and failure events, and subjects were directed to answer only the questions for their own outcome. The first attribution measure was always an open-ended question asking the subject, "Why do you think you *succeeded* (*failed*) on this task?" The other attribution measures were structured response measures.

Eight causal attributions were assessed in the structured response measures. These included the four basic Weiner et al. (1971) causes: high/low general intelligence, task ease/difficulty, good/bad luck, and high/low unusual effort. These were selected for theoretical reasons and because of their frequent use in the literature. The other four attributions were high/low stable effort (stable = consistent), high/low task interest, good/bad mood, and high/low motivation. These have been suggested as important causal factors for this type of situation by open-ended studies (Elig & Frieze, 1975; Frieze, 1976). The attributions were worded in the format suggested by Elig and Frieze (1975) and by Valle and Frieze (1976).[1] Table 2 presents these causes in a three-dimensional taxonomy (cf. Elig & Frieze, 1975; Rosenbaum, 1972).

Two structured response measures were used: unipolar 9-point rating scales and percentage ratings (see Table 1). Both of these were administered with two alternate forms, (a) determination (e.g., "Please rate [indicate] how important you think each of the following factors was in determining your success or failure on the anagram task") and (b) cause (e.g., "Please rate [indicate] the extent to which each of the following factors caused your success or failure on the anagram task"). Each of these was then followed by instructions to respond to a set of success or failure causes. Exact wording of the causes is shown in Table 2 for the success and failure conditions. Structured response measures were (a) rating scale of determinance, (b) percentage scale of determinance, (c) rating scale of causality, and (d) percentage scale of causality. With the open-ended measure, this resulted in a total of five different attribution measures.

The two forms were needed for alternate-form reliability estimates for the scale and percentage methods of assessing causal attributions. Reliability estimates for the open-ended measure were based on intercoder reliability. Since these causal attributions represent a causal analysis of a particular success–failure event, other forms of reliability estimates such as test–retest or coefficient alpha were not appropriate.

Subjects were given the four structured attribution measures and one unstructured attribution measure in a within-subject design. Sixteen orders of the four structured measures were used in a $2 \times 2 \times 2 \times 2$ variation of (a) whether the two measures using the same method were together or separate, (b) whether the scale or percentage method was asked first, and (c and d) whether the determination form or the causality form was asked first for the percentage method and for the scale method. To an unknown extent, this within-subject design will lead to an inflation of intermethod correlation estimates. Subjects may strive for consistency in their responses even when they are instructed to start each measure afresh and not to look forward or back in the test sheets. Such a problem confronts any assessment of

[1] Another issue, not dealt with in this article, is the way in which attributions are worded. This also needs to be systematically analyzed.

Table 2
Measured Causal Attributions Varying According to Stability, Locus of Control, and Intentionality of the Attribution

Stability	Locus of control: Internal	Locus of control: External
Stable		
Unintentional	1. Your high (low) general intelligence	2. How easy (difficult) this type of task is
Intentional	5. The high (low) level of effort which you consistently demonstrate in whatever you do 8. Your high (low) desire to do well in everything you do	
Unstable		
Unintentional	7. Your good (bad) mood	3. Good (bad) luck
Intentional	4. How high (low) your interest in this task was 6. The unusually high (low) effort which you put forth in doing this task	

Note. Numbers indicate the order in which the attributions were presented. Failure wordings are in parentheses.

a momentary state rather than of a stable trait. However, since our interest is in the pattern of correlations rather than in the overall absolute levels, this problem was not too troublesome. Varying order also allowed the assessment of order effects, but since no consistent order effects were found, the results for various orders are collapsed in the discussion of results.

Procedure

The experiment was administered during class time by a male experimenter in five classes. Subjects were told the following:

> In a few minutes you will be asked to do a task consisting of 15 anagrams. An anagram is a group of scramble letters that can be unscrambled to form a word . . . . The brightest 25% of college students can solve at least eight of these anagrams. If you solve eight or more of these anagrams, you will have succeeded at the task; if you solve seven or less of the anagrams, you will have failed on this task. . . .

Subjects were given 30 sec to answer each of the 15 anagrams. The difficulty of the anagrams was manipulated so that half of the subjects received a set of mostly easy anagrams that led them to succeed (e.g., MNEGAA, WADNET, BOLWE), and the other half of the subjects was given a set of mostly difficult anagrams that led them to fail (e.g., SEALGT, IUMSC, OOLRUC) (Bar-Tal & Frieze, 1977).

After completing the anagram task, subjects were asked to total the number of anagrams solved and to rate their subjective feelings of success and failure on a 9-point scale. Subjects were then given as much time as they needed to answer the attribution questions previously discussed and a final set of questions that assessed the face validity of the attribution measures. Subjects were asked for their general impressions of the methods and then ranked them for difficulty and for global impressions of best and worst.

Subjects answered the questions at their own pace; no subject required more than 45 minutes. In each class, when all students were finished, the purpose and general nature of the study were discussed. All subjects were debriefed on the deceptions involved in the presentation of the anagrams task.

Results and Discussion

Although the majority of subjects responded to the success–failure manipulation of anagram difficulty, there were a few subjects who did not. Thirty-six subjects who were given easy anagrams failed to solve eight of them and therefore failed the success criterion. Seventeen other subjects made up words for enough of the unsolvable anagrams to score a "success." This raised a question about whether these 53 subjects should be included in the analyses. A preliminary analysis indicated that there were no systematic differences in the responses of these "erring" subjects as compared to the responses of the other subjects. Therefore, all subjects were included in the analyses listed below. Similar data were obtained when these 53 subjects were eliminated from the analyses.

Table 3
Open-Ended Responses

Attribution category	Equivalent structured measure	Intercoder reliability[a]	No. subjects mentioning	% codable responses[b]
Ability	Intelligence	.91	51	20.8
Task difficulty	Task difficulty	.99	65	26.5
Luck	Luck	1.00	2	.8
Intrinsic motives	Interest	.97	17	6.9
Stable effort	Stable effort	.57	38	15.5
Unstable effort	Unstable effort	.51	11	4.5
Mood	Mood	.91	34	13.9
Personality	—	.70	8	3.3
Task × Ability interaction	—	.74	19	7.8

[a] $n = 252$. These are correlations of the frequency of the attribution being coded for the subject.
[b] A total of 247 attributions were made that were codable; that is, they did not simply repeat the outcome nor explain the process of labeling the outcome a success or failure. One codable attribution was given by 102 subjects, whereas 64 subjects made more than one codable attribution.

Open-Ended Attributions

The responses to the open-ended attribution measure were coded according to the scheme developed by Elig and Frieze (1975). In this coding scheme, each subject's response is segmented into phrases containing individual causes, each of which can be scored for the specific attribution category and for the dimensions of stability, location of cause, and intentionality. The index of each attribution category (such as ability and task ease–task difficulty) used in this study is the number of times it was mentioned by the subject. Two coders coded all responses; the percentage of agreement for the codings ranged between 82.8% and 93.5%. Percentage agreement, although a useful concept, is not a reliability estimate. Reliability was estimated by using the correlations reported in Table 3.

Table 3 also lists the attributions found for the open-ended question, and it shows that all but a small proportion of these attributions were also measured by the structured response measures. Two types of responses are not shown in Table 3. Sixty-one responses (16.4% of total responses) simply repeated the outcome or denied the outcome. Almost all of these responses were from the subjects who had failed to follow instructions. Another 65 responses (17.5% of total responses) were uncodable as attributions. Most of these responses were from subjects who misunderstood the question as asking for the reasons why they labeled the outcome as a success or failure rather than asking for the causes of the outcome.

Intertest Correlation Validity

Interest correlation validities (convergent and discriminant) were assessed in multivariable–multimethod matrices (Campbell & Fiske, 1959; Magnusson, 1967). Since alternate forms (cause and determination) of the structured response methods were used, separate multivariable–multimethod matrices were prepared for each. Table 4 presents the causal forms of the structured method. The matrix for the determination forms was highly similar.[2]

Factor analysis procedures were used in the interpretation of these validities. The factor-analytic solution chosen was principal components analysis with varimax rotation. This solution accounts for reliable true variance with independent factors. We were most interested in the variance common to two or more attribution measures but had to allow

[2] For purposes of brevity, much of the specific comparison data obtained has been omitted from this article. These data are available on request from the authors.

Note. Reliability estimates appear in the main diagonal. Italics indicate convergent validities. The cause alternate form is presented here for the percent and scale methods. (The determination alternate form is available from the authors.) The main diagonal is alternate form reliability for the structured methods and intercoder reliability for the open response method. $n = 252$.

[a] Task ease–difficulty.

[b] Stable effort.

[c] Unstable effort.

[d] Motives category includes the equivalent of both interest and motivation attributions.

for specific factors to emerge. Table 5 gives the factor loadings of the factor analysis of the multivariable–multimethod matrix presented in Table 4.[3] This analysis accounts for 91% of the reliable variance.

The main diagonal of the matrix (Table 4) gives the reliability estimates for attribution-method unit. For the structured methods, these are alternate form estimates; for the open response method, they are intercoder reliabilities. With few exceptions, these are satisfactorily high. The open response measure shows low reliabilities for the effort attributions and shows generally low communalities indicating a need for further refinement of coding instructions to achieve more uniform, acceptable reliabilities for this measure.

The monomethod triangles (under the reliability diagonals) show the intercorrelations of the attributions measured the same way. It is obvious that the open response measure shows the smallest (in absolute value) intercorrelations, indicating either relatively good independence for the attributions measured or a poor representation of the true interrelationships of the attributions. The true correlations may be attenuated by the small range of frequencies of the open response attributions.

The monomethod triangle for the open response method is more similar to the triangle for the percentage than for the scale method. In part, this seems due to the quasi-ipsative nature of the method. No subject in this study gave more than four responses to the open-ended question; thus, once an attribution was made, there was less chance for any other attribution to be made also, inducing small negative correlations. Negative correlations were directly induced by the ipsative percentage measures. The relatively high positive intercorrelations of the attributions measured

[3] Because the percentage measures are ipsative, one percentage measure had to be dropped from the analysis. Interest was dropped in the analysis reported here. Though this is not a totally satisfactory solution, it does eliminate the singularity problem. Interest is included in other analyses, which are available from the authors.

by the scale method may in part have been due to a response bias of some subjects to use only one part of the 9-point scale. This was a response bias that cannot influence the percentage method or the open response method. Method variance can thus be seen to influence the monomethod intercorrelation pattern. The percentage method and the open response method seem to present a pattern different from the one evident in the scale measures.

Factor analyses can aid us in clarifying these patterns. Returning our attention to Table 5, we find the major evidence for method variance in the factor loadings of the open response measures, which form distinct method factors (Factors 7 and 8). However, with the exception of the intelligence attribution, the structured measures of a specific attribution both load on the same factor (see Footnote 3). Also, the monomethod blocks of the structured methods can be factor analyzed separately to clarify their patterns of correlations and the role of method variance. (The open response measure cannot be factor analyzed within method, since there is no alternate form for it as there are for the structured measures.) Tables 6 and 7 present the factor analyses of percentage and scale measures, respectively. The factors in these analyses account for 97% and 100% of the reliable variance of the percentage and scale measures, respectively. The strongest similarity between the percentage and scale monomethod triangles of the multivariable–multimethod matrix was that in each triangle, the largest correlation was for stable effort with motivation (motives in the open measure). These two attributions form the nucleus of the strongest factor (which appears to be a stable achievement factor) in all analyses. The analyses also agree to having mood and luck constituting independent factors.

There are some disagreements between the scale and percentage measures. Factor 1 includes task ease–difficulty for percentage measures and intelligence for scale measures. The factor analysis of the scale measures is more easily interpreted than that of the percentage measures. Factor 2 of the scale analysis can be called *unstable achievement*. Interest in a task should generate unusual effort leading to achievement. Interest and unstable effort correlate when measured by scale cause and scale determination, .52 and .43, respectively, indicating only 27% and 18% overlap in variance, respectively.

Tables 6 and 7 exhibit remarkably clear

Table 6
Factor Loadings of Percentage Measures

Attribution–alternate form	Factor 1	2	3	4	5	Communality

structures. The alternate forms of the structured methods have similar loadings, substantiating their interchangeability.

Returning our attention to Table 4, we note the convergent validities. The convergence of the two structured response methods seems high enough to warrant our further attention. The range of these validities is .43 to .63 for cause measures and .30 to .69 for determination measures. For atttributions measured by cause, there is a mean overlap of 31.1% in variation of the structured methods, whereas the mean is 30.4% for the determination measures.

The convergence of the two structured methods can be clearly seen in Table 5. In this analysis, the scale and percentage measures of an attribution have their highest loading on the same factor except for intelligence. The two structured measures of intelligence converge to the point of loading on the same two factors. (Interest measured by percentages was not in the analysis; see Footnote 3.)

The convergent validities of the open response measure with the structured measures are woefully low (ranging from .00 to .37). These figures indicate that two studies claiming to measure the same attribution, one with a structured measure and one with the open response measure, will only have an average of 4.7% of the variance in common (and a maximum of 14%), with the remainder of the variance being due to noncommon factors (method and error). Mood is the only open response measure to show any amount of convergence. It correlated .37 with the percentage measure and .22 with the scale measure. Mood is the only open response measure to load on the same factor as its structured equivalent (see Table 5).

On either side of the convergent validity diagonals lie heterovariable–heteromethod triangles. Correlations in these triangles are of variables having neither trait nor method variance in common. From this consideration follows the second type of validity, discriminant validity. Discriminant validity is shown when a validity diagonal value is higher than the values lying in its column and row in the heterovariable–heteromethod triangles. For example, attributions to intelligence measured in percentages should correlate more highly with intelligence measured by a scale than they correlate with any other attribution measured by a scale.

The structured responses discriminate fairly well between variables. For the cause form,

no convergent validity estimate is exceeded by a heterovariable–heteromethod value. In the determination form, only task ease–difficulty is problematic. Its convergent validity is exceeded by four other values. This relative lack of discrimination showed up in the factor analysis of the determination form (Table 6) by task ease–difficulty loading somewhat on every factor.

The discrimination shown by the open response method is not nearly as good. Only mood always discriminated. The other attributions failed to show discrimination an average of 4.7 times out of 13 comparisons. It seems reasonable to blame the open response rather than the structured response measures for this lack of discrimination, since good discrimination was shown between the structured measures themselves.

As predicted, results indicate some superiority of structured measures. Structured response reliabilities are higher and are substantiated by communalities, whereas the open response measure intercoder reliabilities are not substantiated by communalities. Convergent and discriminant validities for structured measures are satisfactory, whereas open response convergent validities are low (except for mood). Expect for mood, other open response convergence values are exceeded by an average of one third of the values in their row and column of the heterovariable–heteromethod triangles, indicating poor discrimination.

Face Validation

The second hypothesis concerns the reactions of those subjects whose attributions were being measured. This hypothesis states that to subjects, the face appearance of the open response measure will be more positive than that of either structured response measure. Table 8 presents the frequency with which the subjects termed each method easiest, hardest, best, and worst. As can be seen, subjects differed in ranking the methods on all criteria. Contrary to the hypothesis, however, the differences are not between the open response method compared with structured methods. There were no significant differences between the open response and scale methods; even the largest difference between these methods on the evaluation of best is not significant, $\chi^2(1) = 2.4$. Differences arose from a general disliking of the percentage method. Subjects said they felt that the percentage measure was hard to compute and was not the best reflection of what they felt were the reasons for the outcome.

Table 8
Frequency of Attribution Measurement Methods Selected as Easiest, Hardest, Best, and Worst

	Method			
Evaluation	Open response	Scale	Percent	χ^2
Easiest	76	79	47	9.282**
Hardest	52	49	97	21.909***
Best	77	58	47	7.595*
Worst	45	51	89	18.462***

* $p < .05$.
** $p < .01$.
*** $p < .001$.

Outcome Effects

The final analysis concerned the variations across the methods for success as compared with failure conditions. Results of the analysis of variance for each attribution are presented in Table 9. As can be seen, success was more attributed than failure to ability, stable effort, and motivation for all four structured measures. These outcome effects were not found for the open response measures. There was convergence of the open response measure and both forms of the percentage method (but not the scale method) in that both had greater attributions to low interest and task difficulty for failure than to high interest or task ease for success. Both scale measures also yielded an outcome effect such that success was more attributed to luck, unstable effort, and mood.

Conclusions

As predicted, open-ended response measures of causal attributions have poorer intertest validity and reliability than structured response measures. However, contrary to prediction, structured scale measures were seen

Table 9
Mean Attributions for Success and Failure

Outcome and attribution	Structured response measure				Open response measure
	Percentage		9-point scale		
	Cause	Determination	Cause	Determination

** $p < .01$.
*** $p < .001$.

by subjects as easy to respond to, like the open-ended measures. Percentage ratings were seen by these subjects as having the least face validity. Thus, one of the postulated advantages of the percentage measure was not confirmed. And a supposed weakness of scale measures was not found. Thus, at least for college students solving anagrams or doing similar tasks in which the basic causal categories are well understood, the scale method is clearly a superior technique. This strong support for the scale method of independent assessment of the contribution of various causal factors also confirms findings of Deaux and Farris (Note 1), who used other criteria for their conclusions. They also found little support for the percentage method.

Although open-ended procedures are weaker on the basis of psychometric criteria than scale ratings, they have utility for the researcher who is asking for causal attributions in a new situation. Clearly, people use different categories of causal explanations in different settings (e.g., Elig & Frieze, 1975), and without open-ended pretesting, the experimenter cannot know which causal factors to include in structured measures. Using an open-ended question in later stages of research can serve as a continuing validation of the attribution scales that subjects are asked to rate.

Data from the factor analyses and the success–failure comparisons suggest that open-ended and scale and percentage ratings not only vary in their psychometric properties but also yield different types of data. Hypotheses that concern particular causal attributions can be supported by one type of measurement

and disconfirmed by another; this was demonstrated in the outcome effects reported here.

The attributional measures discussed in this article have been the measures typically used and are representative of three general methods of attribution measurement. Other methods and other within-method variations are possible (e.g., "How much ability did he have?" vs. "How much was ability a cause of his success?"). Many of these possible variations have been used in attribution research. As indicated in this article, these measurement variations may account for some of the discrepancies in the attribution literature.

Fiske (1971) has suggested that in cases in which multiple measures yield conflicting results, the construct be operationally defined by a single measure. These are multiple criteria for selection of a measure, but many of them would lead to the use of the scale measure for attribution research. Results reported here indicate that scale measures have moderately good intermethod correlations with percentage measures, do not force intercorrelations among attributions, and have good face validity. Another important criterion for selecting the specific measurement technique that defines the construct is the construct validity of various procedures. Other data not reported here (see Elig & Frieze, Note 6) indicate that the scale method used in this study provides generally better support for some of the basic theoretical relationships between causal attributions and future expectancies and affect than do either the percentage or open response methods. Even if attribution researchers do not agree on a single measurement technique, these reliability and validity issues should be carefully considered before selecting the measures to be used in future investigations of causal attributions.

Received June 23, 1978 ■

Editors Named for New *Journal of Personality and Social Psychology*

The Publications and Communications Board has named Melvin Manis, Ivan D. Steiner, and Robert Hogan to edit the *Journal of Personality and Social Psychology* (JPSP), which will appear in a new format in January 1980. The affiliations of the new editors are, respectively, University of Michigan and Veteran's Hospital, Ann Arbor; University of Massachusetts; and Johns Hopkins University. Manis will edit the section on ATTITUDES AND SOCIAL COGNITION, Steiner the section on INTERPERSONAL RELATIONS AND GROUP PROCESSES, and Hogan the section on PERSONALITY PROCESSES AND INDIVIDUAL DIFFERENCES.

An announcement on the restructuring of JPSP appeared on p. 668 of the June 1978 issue of JPSP. As indicated at that time, the three editors will work independently with separate groups of advisory editors. Their acceptances will appear as distinct sections in monthly issues of JPSP. Detailed descriptions of each section's coverage appear on pages 468–469 of the March issue of JPSP.

Authors should submit manuscripts to the appropriate section editor as follows:

ATTITUDES AND SOCIAL COGNITION

April 1 through June 15:

Melvin Manis
c/o Anita DeVivo
Suite 700
1400 North Uhle Street
Arlington, Virginia 22201

After June 15:

Melvin Manis
Research Center for Group Dynamics
Institute for Social Research
University of Michigan
Ann Arbor, Michigan 48104

INTERPERSONAL RELATIONS AND GROUP PROCESSES

Ivan D. Steiner

Bargaining Behavior

Edited by Heinz Sauermann. 1978. X, 375 pp. (Contributions to Experimental Economics, Vol. 7). Cloth DM 78.–

Coalition Forming Behavior

Edited by Heinz Sauermann. 1978. X, 375 pp. (Contributions to Experimental Economics, Vol. 8). Cloth DM 78.–

Both volumes contain recent experimental results in the field of multivariable decision behavior. Numerous factors which influence the behavior of subjects in conflict situations are isolated and analyzed. The necessity of interdisciplinary cooperation to develop adequate theories of conflict resolution becomes obvious. Both books present various behavioral approaches and theoretical concepts to explain the observed decision behavior of subjects and to improve the traditional decision theories. Volume 7 focuses on bilateral bargaining problems. In Volume 8 the decision behavior in multilateral decision situations is analyzed. Most contributions discuss the coalition forming behavior especially in characteristic function games.

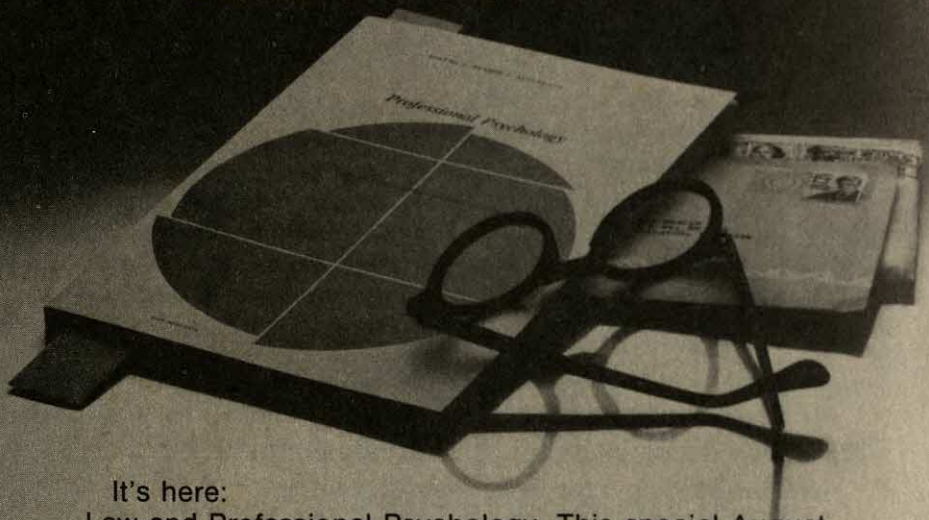
NOW: INFORMATION ABOUT THE LAW AND PSYCHOLOGY.



It's here:
Law and Professional Psychology. This special August 1978 issue of **Professional Psychology** brings you thirteen original articles full of fresh thought and constructive recommendations on the issues that vitally affect your day-to-day practice. You'll find precautions you may take to protect yourself as a professional and a plan for improving investigations of malpractice claims. Expert witness testimony, jury selection, civil commitment, confidentiality and privilege, minor's consent to treatment, and the use of psychological devices are critically examined.

Send your order today. And soon you'll receive this special issue.

Single copies of the issue are available for $5 each. All orders $25 or less must be prepaid. Make and send checks payable to:

American Psychological Association
Order Department
1200 17th Street, N.W.
Washington, D.C. 20036

Enclosed is $_____ for ___ copies of **Professional Psychology's** special issue—Law and Professional Psychology—at $5.00 each.

Understanding Social Psychology

Revised Edition *Just Published*

Worchel & Cooper

Stephen Worchel
University of Virginia

Joel Cooper
Princeton University

The **Revised Edition** of **Understanding Social Psychology** keeps abreast of the rapid growth in the field of social psychology. Each chapter has been thoroughly revised and updated to reflect current trends. This currency has been achieved without sacrificing the historical perspective presented in the first edition.

Special Features

- ★ "Real world" incidents are used at the beginning of each chapter.
- ★ Excellent coverage of attribution theories.
- ★ Very thorough coverage of all traditional areas of social psychology.
- ★ Separate chapter on environmental psychology.
- ★ Includes update on classic theories and research.

Changes

- ★ New chapter on socialization.
- ★ New coverage of: locus of control, learned helplessness, biases in attribution, social power, trust, groups, conflict mediation, theories of crowding.
- ★ Glossary.
- ★ Suggested readings at the end of the chapters.
- ★ **Student Study Guide** written by Carl I. Greenberg, University of Nebraska, Omaha, with learning objectives, multiple choice questions, essays, and student projects.

The Journal of Personality and Social Psychology publishes original reports of research, methodology, theory, criticism, and literature review in the fields of personality and social psychology of normal processes and populations. Submitted manuscripts should delineate an important question and provide a clear answer to it. In the case of research reports, this will often require demonstration that the reported results are generalizable beyond a single research setting. Consult the editorial in the January 1976 issue (Vol. 33, pp. 1–7) for a detailed statement of policies and instructions to authors.

Manuscripts: Submit manuscripts in quadruplicate, prepared according to the *Publication Manual of the American Psychological Association* (2nd ed.). Copies should be highly legible and will not be returned to authors unless they are original typewritten copies. Mail manuscripts according to instructions on p. 809.

Required supplementary information: Manuscripts cannot be reviewed for publication unless the author provides supplementary information in the following categories: (a) a cover letter that indicates the relation (or the lack of relation) of the submitted manuscript to other papers by the same author(s) that are currently submitted, in press, or recently published; (b) one copy of each such related paper; (c) one copy of a statement of the procedures of the research reported in the submitted manuscript in sufficient detail to serve as a guide for conduct of an exact replication; and (d) one copy of the summary tables (e.g., correlation tables, analysis of variance summaries) for the *major* analyses reported. If it appears that the supplementary materials in categories (c) or (d) might be bulky, the author should exercise judgment and restaint in selecting what to send. It is not necessary to send supplementary material that repeats verbatim manuscript content.

After a manuscript is accepted, authors will be expected to provide assurance that their data are available in unanalyzed form for reanalyses by other investigators and that their research procedures were consistent with the American Psychological Association's published principles of research ethics, except insofar as may be detailed otherwise in the manuscript.

Copyright and Permission: All rights reserved. Written permission must be obtained from the American Psychological Association for copying or reprinting text of more than 500 words, tables, or figures. Permission is normally granted contingent upon like permission of the author, inclusion of the APA copyright notice on the first page of reproduced material, and payment of a fee of $10 per page, table, or figure. Abstracting is permitted with credit to the source. Permissions and fees are waived for authors who wish to reproduce their own material for personal use; fees only are waived for authors who wish to use their own material commercially. Permission and fees are waived for the photocopying of isolated articles for nonprofit classroom or library reserve use by instructors and educational institutions. Libraries are permitted to photocopy beyond the limits of U.S. copyright law: (1) those post-1977 articles with a code at the bottom of the first page, provided the per-copy fee indicated in the code is paid through the Copyright Clearance Center, P.O. Box 765, Schenectady, NY 12301; (2) pre-1978 articles, provided that the per-copy fee stated in the Publishers' Fee List is paid through the Copyright Clearance Center, P.O. Box 765, Schenectady, NY 12301. Address requests for reprint permission to the Permissions Office, APA, 1200 Seventeenth Street, N.W., Washington, D.C. 20036.

Subscriptions: Subscriptions are available on a calendar year basis only (January through December). Nonmember rates for 1979: $60 domestic, $64 foreign, $6 single issue. APA member rate: $20. Write to Subscription Section, APA.

Change of Address: Send change of address notice and a recent mailing label to the attention of the Subscription Section, APA, 30 days prior to the actual change of address. APA will not replace undelivered copies resulting from address changes; journals will be forwarded only if subscribers notify the local post office in writing that they will guarantee second-class forwarding postage.

Reprints: Authors may order reprints of their articles from the printer when they receive proofs.

Back Issues and Back Volumes: For information regarding back issues or back volumes write to Order Department, APA.

Microform Editions: For information regarding microform editions write to any of the following: Johnson Associates, Inc., P.O. Box 1017, Greenwich, Connecticut 06830; University Microfilms, Ann Arbor, Michigan 48106; or Princeton Microfilms, Princeton, New Jersey 08540.

Published monthly in one volume per year by the American Psychological Association, Inc., 1200 Seventeenth Street, N.W., Washington, D.C. 20036. Printed in the U.S.A. Second-class postage paid at Arlington, Va., and at additional mailing offices.

The Popularity of Conspiracy Theories of Presidential Assassination: A Bayesian Analysis

Clark McCauley and Susan Jacques
Bryn Mawr College

Journalist Tom Bethell has advanced the hypothesis that conspiracy explanations of Presidential assassination are popular because people have an irrational need to explain big and important events with proportionately big and important causes. This is a species of consistency hypothesis and clearly predicts that a shot that kills the President is more likely than a miss to be attributed to a conspiracy. Four studies are reported that support this prediction. Three of the four studies provided a check on whether conspiracy was overly favored, in the case of successful assassination, by comparison with the normative Bayesian formulation. No evidence of this kind of departure from rationality was found. It appears that people associate conspiracy with successful assassination, not because of any kind of special need for proportionality of cause and effect, but because of a belief that conspiracies are more effective and successful than lone assassins.

John F. Kennedy was shot dead in Dallas in 1963, and the Warren Commission reported in 1964 that the assassination was the work of a lone assassin, Lee Harvey Oswald. In 1979, the issue is evidently not yet settled. The House Select Committee on Assassinations has concluded its work, still uncertain about a fourth shot. Polls indicate that the majority of Americans, around 80% in fact, believe that others besides Oswald were involved in the assassination (Gallup, 1976). Books and articles theorizing about the assassination are still appearing regularly. Recent examples of the genre include *They've Killed the President* by Robert Sam Anson (1975), *Coincidence or Conspiracy?* by Bernard Fensterwald (1977) and the Committee to Investigate Assassinations, and *Legend: The Secret World of Lee Harvey Oswald* by Edward Jay Epstein (1978). Clearly, Americans are not satisfied with the conclusion of the Warren Commission.

Whatever the merits or defects of the Warren Commission report, the continuing popularity of conspiracy theories is itself a remarkable fact. Most events, no matter how traumatic, do not last in the public awareness as the Kennedy assassination has. Most events, no matter how great, quickly drop from headlines to history. Accidents, scandals, great men, and even wars are left behind, forgotten or at least much faded. But

Diary No. 69
Date 2/11/1979

new books about John F. Kennedy's assassination are selling 15 years after the event, selling in supermarkets and in drug stores against competition from pop psychology and sex books. It is the premise of this article that the continued popularity of conspiracy theories of the Kennedy assassination is a surprising social fact that is worthy of investigation.

The studies reported here are aimed at testing one hypothesis about the popularity of conspiracy theories, namely, that people irrationally seek big causes to explain big effects. According to this hypothesis, advanced by journalist Tom Bethell in *The Washington Monthly* (1975), a lone assassin is too small and insignificant a cause to provide a satisfactory explanation for such large effects on policy and people as follow a President's death.

> We are expected to believe, according to the official explanation, that the Johnson Administration and all that it entailed, possibly including the debacle of Vietnam, was set in motion by one man who had quarreled with his wife; who had, as it were, gotten out of bed on the wrong side that morning, and found a gun lying there.
>
> The cause doesn't fit the effect. But the fact is, when great power is vested in one man, as in the President of the United States, it is always possible that a small cause (a microbe in his blood, for example, leading to a fatal disease, leading to a new President, leading to a "Vietnam") can trigger a large effect.
>
> In such cases many people will seek a new cause that is commensurate with the effect—seek, in other words, large and global explanations that thereby imbue the event with appropriate meaning. In the case of the Kennedy assassination, of course, this means looking for a conspiracy—preferably a large one. (Bethell, 1975, p. 39)

Bethell's hypothesis is recognizable as a species of consistency hypothesis, of which dissonance theory is the most prominent previous example (Brown, 1965, chapter 11). A need for consistency of cause and effect clearly implies that the need for a big cause should be greater, the greater the effect to be explained. Thus the Bethell hypothesis predicts that the perceived probability of a conspiracy should be much higher when the President is shot at and killed than when he is shot at but missed. Study 1 was designed to test this prediction.

Study 1

Method

Subjects. Subjects were 20 undergraduate students of Bryn Mawr and Haverford Colleges, 10 female and 10 male.

Questionnaire. The questionnaire consisted of two pages. On the top of each page was the following introduction: "News reports of violent events and their causes are sometimes surprising and sometimes not. This study aims to measure your personal feeling about the likelihood of several stories of several events." Below the introduction was typed a headline in capital letters: "A MAN SHOOTS AT THE PRESIDENT AND MISSES" or "A MAN SHOOTS AT THE PRESIDENT AND KILLS HIM." On each page, after the headline, the same two questions appeared: "What is the probability that this man is acting alone and unaided?" and "What is the probability that this man is acting as a member of a group organized to kill the president?"

Procedure. The order of the two pages was reversed for half the subjects. Two female experimenters each obtained 10 completed questionnaires.

Results

In this and succeeding studies, it is the relative probabilities associated with group and individual explanations of assassination that are of interest. These relative probabilities are naturally expressed as ratios, and we report our data in the form of median ratios. Mean ratios do not properly represent the central tendency of distributions of these ratios, since a few ratios in every distribution are likely to be very extreme values. When most subjects are giving ratios such as 2:1, 5:1, or 1:4, one subject giving a ratio of 100:1 can make the mean ratio totally unrepresentative. Thus, means and parametric statistics are inappropriate with our data, and we use medians and nonparametric statistics instead.

The data of Study 1 did not appear to depend on the order of the pages of the questionnaire or on the experimenter, so the data of all 20 subjects were pooled for analysis.

The first column of Table 1 shows that the median odds for conspiracy were 1:1 when the President had been killed, but were 1:2 when the President had been missed. That is, the likelihood of conspiracy relative to the likelihood of a lone assassin was typically seen as greater when the assassination was

successful. We can use a sign test to test the significance of this tendency. Of the 20 subjects in Study 1, 13 subjects gave odds of conspiracy higher when the President was killed than when he was missed. Six subjects indicated no difference in these odds, and one subject reported the reverse difference in odds. These data indicate ($p < .05$ by one-tailed sign test for correlated samples) that a successful assassination is more likely than a failure to be attributed to a conspiracy.

Discussion

Study 1 supported the prediction that information about success or failure of an assassination attempt makes a big difference in the popularity of a conspiracy explanation. This prediction came from the general hypothesis that people need a big cause to explain a big effect. A special need for consistency in the size of cause and effect is not, however, directly demonstrated by the data of Study 1. For instance, it might well be that the effect of information about success comes rationally from a judgment that groups are more effective and likely to succeed than individuals. In order to demonstrate the hypothetical consistency need, it must be shown that people systematically exaggerate the probability of a conspiracy beyond what the news of a successful assassination rationally calls for. Clearly, this demonstration requires a formulation of the rational impact of information, and Bayes' rule provides just this normative formulation.

In probability form, Bayes' rule requires that

$$p(\text{conspiracy/President killed}) = p(\text{conspiracy}) \cdot \frac{p(\text{President killed/conspiracy})}{p(\text{President killed})}.$$

Note that this formulation calls for revision in the prior probability of a conspiracy to the extent that the ratio reflecting the efficacy of a conspiracy—p (President dead/conspiracy)/p(President dead)—is greater than 1.0. More useful for present purposes is Bayes' rule in odds form:

$$\frac{p(\text{conspiracy/President killed})}{p(\text{individual/President killed})} = \frac{p(\text{conspiracy})}{p(\text{individual})} \cdot \frac{p(\text{President killed/conspiracy})}{p(\text{President killed/individual})}. \quad (1)$$

This form indicates that the odds favoring a conspiracy over an individual assassin, given that the President is killed, need to be revised and increased over the prior odds favoring a conspiracy to the extent that a conspiracy is seen as more likely than an individual to succeed in killing the President. If the posterior odds are found to be systematically higher than called for by the prior odds and the efficacy ratio, then the hypothesis of a consistency need to explain the departure from rational prescription would be strongly supported.

Studies 2 and 3

Method

Subjects. The subjects of Study 2 were six males and six females recruited individually by a female experimenter in the environs of the Bryn Mawr train station. The 12 subjects ranged in (estimated) age from early 20s to late 50s. Subjects of Study 3 were 15 males and 9 females recruited by a different female experimenter in a restaurant and bar near Bryn Mawr College. These subjects appeared to be in their 20s and 30s and were generally approached as same-sex groups (though subjects filled out the questionnaire without discussion with their friends).

Questionnaire. The questionnaire for Studies 2 and 3 was composed of four pages, two of which asked questions much like the two questions used in Study 1. At the top of these two pages was the instruction: "Imagine the following news headline": There followed, on one page, "MAN SHOOTS, KILLS PRESIDENT," and on the other page, "MAN SHOOTS AT PRESIDENT, MISSES." On both pages the succeeding question was the same: "Which is more likely? (A) The man is acting alone and unaided or (B) the man is acting as a member of an organized group." The question continued with a quantification: "If you checked A, how much more likely is A? (Twice as likely as B? Three times as likely? Five times? Ten times?)." The parallel alternative was also given: "If you checked B . . . ," etc.

The prior odds favoring conspiracy were assessed on a third page: "The next person to try to kill the President will likely be . . . (check one)." There fol-

lowed the same A versus B choice and the same quantification of that choice as just described for the first two pages.

The likelihood ratio reflecting the relative efficacy of a conspiracy was assessed on a fourth page, as follows: "Suppose that a man acting alone and unaided is trying to kill the President. Suppose also that a man acting as a member of an organized group or conspiracy is trying to kill the President. Which is more likely to succeed in killing the President?" There followed the same A versus B choice and quantification of that choice as already described.

Procedure. In Study 2, the prior-odds question was always on the last page, and the 6 possible orders of the other three pages appeared twice each to form the 12 questionnaires. In Study 3, all 24 possible orders of the four pages appeared once to make up the 24 questionnaires.

Results

Columns 2 and 3 in Table 1 show that, as in Study 1, the conspiracy explanation was typically more popular when the President was killed than when he was missed (median odds of 2:1 vs. 1:3 for Study 2, and median odds of 2.5:1 vs. 1:3 for Study 3). This result is confirmed ($p < .05$ by one-tailed sign test for correlated samples) by noting that 7 subjects in Study 2 judged conspiracy odds higher when the President was killed than when he was missed, whereas only 1 judged the reverse. For Study 3, the corresponding numbers were 13 and 2, respectively (also $p < .05$ by sign test).

The two additional questions and the odds format of all the questions permit assessment of the degree to which subjects exaggerate the chance of conspiracy. For each subject, the posterior odds of conspiracy given that the President was killed were compared with the product of the prior odds for conspiracy and the efficacy ratio. In Study 2, 5 subjects gave posterior odds of conspiracy higher than required by Bayes' rule, and 6 subjects gave posterior odds too low. In Study 3, 8 subjects gave posterior odds too high, and 13 gave posterior odds too low. Clearly, there is no evidence here of systematic departure from rationality; conspiracy is not overly favored when the President is killed.

Earlier we supposed that higher odds for conspiracy, given successful assassination, might be rational if people believe that groups are more effective than lone assassins. That supposition received some support in Studies 2 and 3, since the median efficacy ratios (third row in Table 1) of 2.5:1 and 2:1 indicate that groups are typically seen as more likely than individuals to succeed in an attempt to kill the President. In Study 2, 9 subjects thought groups were more likely to succeed, 2 subjects thought individuals were more likely to succeed, and 1 subject thought there was no difference ($p < .05$, one-tailed binomial test). In Study 3, 14 subjects thought groups were more effective, and 10 subjects thought the reverse ($p < .27$, one-tailed binomial test, *ns*). Thus, Study 2, but not Study 3, shows significantly more than half the subjects judging groups as more likely than individuals to succeed in an attempt to kill the President.

Study 4

It appears that Studies 2 and 3 have shown that the odds for conspiracy are not exaggerated, compared to the perception of the prior odds of conspiracy and the diagnosticity of the news that the President has been killed. Before accepting this conclusion, however, there is a flaw to be considered in the questionnaire used in Studies 2 and 3. That is, the aim was to ask about prior and posterior odds of conspiracy that differ only in giving the information that the President was killed in the posterior assessment. Unfortunately, the difference between our prior ("The next person to try to kill the President . . .") and our posterior ("Man shoots, kills President") question is two pieces of information: that the attempt got as far as getting a shot off and that the shot was successful. Our efficacy ratio, on the other hand, assessed only the information value of success and not the information value of getting a shot off. In order to be sure that this confounding is not important to our results, we revised the questionnaire and used it in a new study.

Method

Subjects. Subjects were 15 males and 9 females recruited at a shopping center near Bryn Mawr College by the same female experimenter who ran Study 3. The subjects ranged in (estimated) age from early 20s to late 50s.

Table 1
Median Probability Ratio Associated With Conspiracy (Group) Versus Lone Assassin (Individual) Explanations of Presidential Assassination

Probability	Study 1 (n = 20)	Study 2 (n = 12)	Study 3 (n = 24)	Study 4 (n = 24)
$\frac{p(\text{group/President killed})^a}{p(\text{individual/President killed})}$	1:1	2:1	2.5:1	2:1
$\frac{p(\text{group/President missed})^a}{p(\text{individual/President missed})}$	1:2	1:3	1:3	1:2
$\frac{p(\text{President killed/group try})^b}{p(\text{President killed/individual try})}$		2.5:1	2:1	3:1
$\frac{p(\text{group try})}{p(\text{individual try})}$		1:2	2:1	1:1

[a] In each of the four studies, a conspiracy was judged more likely when the President was killed than when the President was missed ($p < .05$ by one-tailed sign test for correlated samples).
[b] In Studies 2 and 4, but not in Study 3, more than half the subjects judged a group more likely to succeed than an individual ($p < .05$ by one-tailed binomial test).

Questionnaire. The questionnaire was identical to that used in Studies 2 and 3 except for the wording of the prior-odds question and the relative efficacy question. Whereas the previous questionnaire asked about "The next person to try to kill the President . . ," the revision asked, "The next person to shoot the President will likely be. . . ." And whereas the previous form asked about the success expected of an individual or group "trying to kill the President," the revision went as follows: "Suppose that a man acting alone and unaided gets a shot at the President. Suppose also that a man acting as a member of an organized group gets a shot at the President. Which is more likely to succeed in shooting and killing the President?"

Procedure. The procedure was the same as in Studies 2 and 3.

Results

Column 4 of Table 1 shows that, as in Studies 1–3, the conspiracy explanation was more favored when the President was killed than when he was missed (median odds of 2:1 vs. 1:2). This result is confirmed by noting that 13 subjects judged conspiracy more likely when the President was killed than when he was missed, whereas only 4 subjects judged the reverse ($p < .05$ by one-tailed sign test for correlated samples).

As in Studies 2 and 3, an analysis at the level of the individual compared the posterior odds of conspiracy with the product of the prior odds for conspiracy and the likelihood ratio giving the relative efficacy of conspiracy. Nine subjects gave posterior odds of conspiracy higher than required by Bayes' rule, and 15 subjects gave posterior odds too low. In short, the results of Study 4 are like those obtained with the flawed questionnaire in Studies 2 and 3. Studies 2–4 are consistent in finding no systematic exaggeration, compared to the Bayesian prescription, of the probability of a conspiracy when the President is killed.

Likewise, the tendency to see groups as more effective than individuals is confirmed in Study 4. The efficacy ratios judged by subjects in Study 4 were for the case of an assassin who had gotten as far as a shot at the President: the relative probability of killing the President for a member of an organized group versus an individual acting alone and unaided. The median efficacy ratio (third row in Table 1) of 3:1 indicates that group members are typically seen as better shots. In Study 4, 19 subjects thought group members were more effective, and 5 subjects thought the reverse ($p < .05$, one-tailed binomial test). Thus, Study 4 shows significantly more than half the subjects judging groups as more likely than individuals to succeed in killing the President, once having gotten off a shot.

"Pure" Data From Studies 1–4

The within-subjects design of the present studies, where each subject answered two

(Study 1) or four (Studies 2–4) questions, raises the possibility of sensitization effects. Perhaps subjects answer a question differently because of biases or hypotheses engendered by having already answered previous questions. In order to be sure that our results do not suffer from sensitization problems, we brought together "pure" data corresponding to the first three rows of Table 1, that is, for the ratios about which we have made claims by statistical test. The "pure" data are from only the first pages of questionnaires, that is, are responses to questions by subjects who had not previously answered other questions. These data cannot therefore be prejudiced by any kind of sensitization effect.

Putting together "pure" data from Studies 1–4, we had 26 judgments of the odds for conspiracy given success (first row in Table 1) and 26 judgments of the odds for conspiracy given failure (second row in Table 1). The median odds for conspiracy when the President was killed were 2:1; they were 1:2 when the President was missed. These two "pure" medians are numerically quite close to the medians for all data in rows 1 and 2 (respectively) of Table 1, indicating that sensitization effects were not a problem for these data. Further, these two "pure" medians are significantly different ($p < .05$ by one-tailed median test) and clearly indicate that in a cross-groups design, we still find that the odds for conspiracy are higher when assassination is successful than when it fails.

Similarly, we put together data from Studies 2–4 to get a total of 15 "pure" judgments of the efficacy ratio (row 3 in Table 1). The median of these 15 efficacy ratios was 2:1, which is numerically close to the medians for all data in row 3 of Table 1. Unfortunately, it is not true that significantly more than half our 15 "pure" subjects saw groups as more effective than individuals (in fact, only 8 of 15 did). Still, we believe that with only 15 judgments, the failure to obtain statistical support cannot be too surprising and that the numerical value of the "pure" median offers some indication that the efficacy ratio data do not suffer from serious sensitization problems.

General Discussion

We began with Tom Bethell's (1975) hypothesis that conspiracy theories of Presidential assassination are popular because of an irrational need for big causes to explain big events. From this hypothesis we predicted that the success or failure of an assassination attempt should make a big difference in the perceived likelihood of conspiracy. Studies 1–4 confirmed this prediction: People are much more likely to entertain a conspiracy explanation when the President is shot and killed than when he is shot at and missed.

This effect is all the more striking given that our manipulation of the information of success and failure was only a few words in an imaginary newspaper headline. We provided none of the richness of detail and description that one might suppose necessary for compounding a conspiracy theory. The cold and abstract nature of our manipulation was intentional, since Bethell's consistency hypothesis depends only on an abstract proportionality of cause and effect, and since we wanted to avoid the possibility of introducing some general cognitive bias in our description. It is clear from our results that the greater popularity of conspiracy explanations when the President is dead is an effect that does not depend on the specifics of a particular assassination story.

Studies 2–4 were aimed at discovering whether the effect of success versus failure is irrational, that is, whether the posterior odds for conspiracy are exaggerated compared to the prior odds for conspiracy and the diagnosticity of the information that the President has been killed. No evidence of such exaggeration was found.

Here it should be noted that the difference between the odds for success when the President is killed and the odds for success when the President is missed—the difference suggested by Bethell's hypothesis and found by us in each of the four studies reported here—might still be irrational in a fashion not tested for in our studies. That is, it might be that the posterior odds for conspiracy are systematically underestimated compared to the prior odds for conspiracy and the diag-

nosticity of the information that the President has been missed.

What we know from all four studies is that

$$\frac{p(\text{group/President killed})}{p(\text{individual/President killed})} > \frac{p(\text{group/President missed})}{p(\text{individual/President missed})}. \quad (2)$$

Bethell's consistency hypothesis suggests that people have an irrational need to see big causes for big effects, which implies an inequality in place of the normative Bayesian equality:

$$\frac{p(\text{group/President killed})}{p(\text{individual/President killed})} > \frac{p(\text{group try})}{p(\text{individual try})} \cdot \frac{p(\text{President killed/group try})}{p(\text{President killed/individual try})}. \quad (3)$$

We tested for this systematic exaggeration and found no evidence of it, that is, no evidence that the left side of Equation 2 is typically too large. But it might yet be true that Equation 2 is irrational to the extent that the right side of it is too small:

$$\frac{p(\text{group/President missed})}{p(\text{individual/President missed})} < \frac{p(\text{group try})}{p(\text{individual try})} \cdot \frac{p(\text{President missed/group try})}{p(\text{President missed/individual try})}. \quad (4)$$

This amounts to the hypothesis that people have an irrational need to see small causes for small effects. Although Equation 4 is also a species of consistency hypothesis, it is different from and less intuitive than Bethell's hypothesis. We did not test for Equation 4, which requires an odds judgment—

$$\frac{p(\text{President missed/group try})}{p(\text{President missed/individual try})}$$

—that we did not ask of our subjects.

Thus, people do associate successful assassination with conspiracy, but not because of an irrational need to find big causes for big effects. Rather, our data indicate that people believe conspiracies are more efficient and effective than lone assassins. Whether conspiracies are in fact more dangerous than lone assassins is unknown, save perhaps to the Federal Bureau of Investigation, but the belief in group efficiency does make sense of the substantial probabilities people attach to conspiracy explanations of Presidential assassination.

The association of successful assassination with conspiracy and the belief in group efficacy make sense in another way. They are an interesting example of support for Kelley's (1967, 1972) analysis of variance model of subjective causality. According to this model, "the more extreme the effect to be attributed, the more likely the attributor is to assume that it entails multiple necessary causes" (Kelley, 1972, p. 6). With the relatively easy assumption that the members of a conspiracy are thought of as multiple necessary causes, it follows from Kelley's model that a conspiracy is seen as more likely when the President is dead—an extreme effect—than when he has been missed.

At this point we must recognize that we have not entirely answered the question with which we began. We set out to understand the popularity of conspiracy explanations of the John F. Kennedy assassination. In one sense we have done that, since the belief that conspiracies are more effective than lone assassinations makes understandable the substantial likelihood of conspiracy that people perceive when the President is killed. But the level of public interest in conspiracy explanations of the Kennedy assassination, as distinct from the level of confidence in these explanations, is yet to be understood. The strength and duration of public interest in conspiracy explanations suggests a strong motive at work, but the Bayesian analysis—a static, cognitive analysis—cannot by itself reveal the motive we seek. If the Bayesian analysis had given us evidence of systematic exaggeration in the probability of conspiracy, we would have inferred the kind of consistency motivation we hypothesized at the beginning of this research. In the absence of this kind of exaggeration, however, we must look elsewhere for the motivation that makes the con-

spiracy explanation of the Kennedy assassination so interesting.

One interesting possibility is that Americans are experiencing a gigantic Zeigarnik effect. Zeigarnik (1927) found that interrupted tasks are remembered better than tasks that are completed. Although this effect dissipated within a day or two for the laboratory tasks Zeigarnik used, stronger effects of the same kind may occur with more involving tasks. It seems likely, for instance, that the same lack of closure Zeigarnik was studying can make a fisherman dwell on the one fish that got away long after he has forgotten the many he boated. Perhaps as long as the official explanation conflicts with a common belief linking successful assassination with conspiracy, Americans will see the John F. Kennedy assassination as the kind of unresolved problem that continues in memory and attention.

Implicit Theories of Relationship: An Intergenerational Study

Marylyn Rands and George Levinger
University of Massachusetts—Amherst

College students and senior citizens two generations apart in age estimated the probabilities of each of 30 behaviors for each of 14 pair relationships varying in their closeness (casual acquaintances, good friends, close relationship, married partners) and in their sex composition. The younger respondents rated the pair relationships of 22-year-olds today, while the older ones rated those of 22-year-old pairs of 50 years ago. The behavior items referred to a variety of social behaviors pertaining to joint activity, self-disclosure, other-enhancement, other-disparagement, physical contact, and norm regulation. Closeness and sex composition of the relationships as well as content of the behaviors strongly affected the probability estimates. The raters' generation also exerted strong effects; today's pairs, especially good or very close heterosexual friends, were believed to be much more likely to express positive and negative feelings and to have physical contact.

How do social relationships of today differ from those of yesterday? And how do they correspond? In what ways have norms changed from generation to generation? Answers to such questions are difficult to come by.

Historical analyses sometimes provide us with theories or hypotheses about contemporary conduct by comparing it with that of earlier times. For instance, in his historical novel *Angle of Repose,* Wallace Stegner (1971) draws a picture of the intimate relationships of three pairs of characters, each pair separated by two generations. The main character is a 58-year-old historian, Lyman Ward, who writes a book about his grandparents' marriage, contrasting it intermittently with his own and that of his 20-year-old secretary, Shelly. Lyman's two grandparents lived together for over 60 years, until parted by death; each suffered the other's transgressions silently, but their relationship deteriorated over the course of their long marriage. Lyman's own long marriage was recently ended, leaving him feeling helpless and betrayed. His secretary, meanwhile, unsure of her commitment, alternately lives with and hides from her lover.

These three pairs display vast differences in their overt behaviors, their expectations of right and wrong, their comforts and discomforts. Lyman's grandparents display stoicism, politeness, discipline, and inhibition toward each other, their kin, and close friends. Lyman and his wife, too, maintain their relationship publicly in the face of private difficulties, but their failure to resolve their problems ultimately results in the breakup of their marriage. In contrast, Shelly's and her lover's on-and-off affair is marked by self-expression, directness, and unpredictability.

This set of characters conveys the idea that norms of interpersonal conduct have changed dramatically over the past century and that each generation both suffers and benefits from its own constellation of circumstances. The novel's message derives from Stegner's per-

This article is based on a master's thesis submitted to the University of Massachusetts by Marylyn Rands (Lacey) with the guidance of the second author and the support of National Science Foundation Grants GS-33641 and BNS 76-02575. For their assistance, we wish to thank the other members of the master's committee, Icek Ajzen and Arnold Well. We are also indebted to Lawrence O'Brien for his valuable help in implementing the multidimensional analyses and to Andy Anderson, Ted Huston, and Myron Wish for their extensive comments.

sonal impressions—from his *theory* of changes in interpersonal conduct from yesterday to today.

Are there ways of confirming such theories about past and present interpersonal relationships? The present study was an effort to do so. It was a systematic attempt to study people's "implicit theories" about pair relationships—people's expectations about what behavior will occur in different pairings. Each of us is assumed to hold expectations for appropriate conduct that depend on our relationship with another, whether as a child, sibling, friend, spouse, parent, co-worker, or colleague.

The term "implicit theory of relationship" was first suggested to us by Wolfe (Note 1), who proposed that people share "notions about what characteristics of relationships should co-occur" (p. 20). Research on such notions appeared to be a way of pursuing our own interest in distinguishing among levels of pair relatedness (Levinger, 1974; Levinger & Snoek, 1972). Before ascertaining what sorts of characteristics are expected to co-occur, however, it seemed important first to discover what behaviors people expect to *occur*, as was explored earlier in our research program by Richard Mack (see Levinger, 1974).

Previous Research

Several previous studies have investigated perceptions of interpersonal relationships. DeSoto and Kuethe (1959) examined male college students' subjective probabilities for expecting positive or negative feelings in hypothetical pairs of male acquaintances. Respondents estimated the probability that, under various conditions, A would like B (or trust, feel superior to, dislike, lie to, listen to, or dominate B, and so on). Respondents were found to assign higher probabilities to positive than to negative affective relations. Some A–B relations were perceived as symmetric, others as asymmetric; some as transitive, others as intransitive.

Marwell and Hage (1970) obtained ratings of 100 different dyadic role relationships—such as father–son, best friend–best friend, landlord–tenant, actor–agent—on a set of 16 scales measuring characteristics of interaction (such as its frequency, the effort required, or its voluntariness). A factor analysis of these ratings uncovered three dimensions of pair relationships: intimacy, visibility, and regulation of behavior.

A third study located cross-cultural generalities in close relationships (Triandis, Vassiliou, & Nassiakou, 1968). American and Greek respondents rated the appropriateness of 120 behaviors (e.g., show concern for, disagree with, kiss, help, argue with other) for 100 dyadic roles. Four factors common to both cultures emerged: affect, intimacy, dominance, and hostility.

In a fourth study, Wish, Deutsch, and Kaplan (1976) searched for fundamental dimensions in people's perceptions of interpersonal relationships by asking subjects to rate 25 "typical" role relationships and 20 of their own interpersonal relationships on scales pertaining to a large variety of traits (such as cooperative–competitive, emotional–intellectual, flexible–rigid). Their multidimensional scaling analysis revealed four major dimensions of relationships, which can be interpreted as mutual cooperativeness, equality, intensity, and informality.

All these studies found aspects of closeness, positivity, and social influence to be important for characterizing variations among social relationships. Only one of these studies (Triandis et al., 1968), however, examined interpersonal *behaviors*, and it did not select those behaviors from any defined population of actions. Nor did any of these studies have an explicit schema for selecting its sample of relationships; the findings did not permit one to draw conclusions about the effects of systematic variations in relationship.

The Present Research

The present work is concerned with the effects of interpersonal closeness on people's perceptions of appropriate behavior in pairs. Following from Levinger and Snoek's (1972) suggestion of a continuum of pair relatedness, Richard Mack had earlier obtained pertinent descriptive data (see Levinger, 1974, pp. 109–111). Mack's study focused on the behaviors of heterosexual couples of four different degrees of intimacy, from "casually acquainted"

to "much in love and fully committed." His informants considered 52 different possible behaviors—from "smile at the other" to "refuse to date other persons"—and rated how likely each behavior was in each of the four sorts of relationships. For most of the behaviors, likelihood of pair interaction was perceived to vary directly with intimacy (see Levinger, 1974, p. 110).

In the present study, it was decided to vary not only the two partners' closeness but also the pair's sex composition, so as to study perceptions of a systematically selected set of pair relationships. Such relationships were to be rated by raters of both sexes who were drawn from two different age groups. A set of guiding hypotheses and questions is listed below.

Relationships: Degree of closeness. It was hypothesized that expectations of interaction would increase as the perceived closeness of a pair increased. According to current conceptions of relationships (Altman & Taylor, 1973; Levinger & Snoek, 1972), the breadth and the intensity of mutual behavior grows along with increasing interpersonal involvement.

Furthermore, respondent characteristics were assumed to affect such expectations. In line with earlier findings in our research program (Levinger, Rands, & Talaber, Note 2), we hypothesized no differences between the judgments by raters of different sex, but we did look for significant age differences. Raters from today's college generation were hypothesized to expect more pair interaction than raters from their grandparents' generation rating young pairs of 50 years ago.

Relationships: Sex composition. We hypothesized that different behaviors would be expected in same-sex pairs than in cross-sex ones, as well as in male–male as compared to female–female pairs. For example, cross-sex pairs would be perceived as more likely to have physical contact than would same-sex pairs, and female–female pairs as more likely to disclose intimacies than would male–male dyads.

Furthermore, it was hypothesized that younger raters would differentiate less between same-sex and cross-sex relationships than would older raters. This hypothesis was based on the assumption that today's sex role stereotypes are less distinct than those of 50 years ago.

Considering the sex of the actor, we hypothesized that raters would judge female partners to be more likely than males to initiate expressive actions, and males to be likely to initiate more actions pertaining to the management of overt activities. Such differences, it was thought, would be greater for older than for younger respondents.

Questions were also posed concerning the perceived likelihood of various sorts of behaviors that might occur in close pairs. We hypothesized that activity-oriented behaviors would be perceived as less affected by the partners' closeness or sex composition than would those expressing positive or negative feelings and that expectations of physical contact would be most affected by variations in closeness and sex composition.

Method

Participants in the study were of two age groups and of two sexes. Each person rated the likelihood of 30 different behaviors for each of 14 relationships. A sample of young, college-age raters judged "typical relationships" between 22-year-old partners today. The age of 22 was chosen to be near enough to that of the college-age respondents while old enough for people to be stably married. A sample of older raters, generally in their 70s, described relationships of 22-year-olds as they recalled them from the time when they themselves were in their early 20s.

Raters

The group of young raters consisted of 40 University of Massachusetts students, half male and half female. They came to group sessions in response to either an announcement in an introductory sociology class or an advertisement posted in the psychology building. Thirty-four raters were paid $1.50 each for filling out the questionnaire, and six chose to receive experimental credit from a psychology class. They ranged in age from 18 to 27 years, with a mean age of 19.9 years.

The group of older raters were 40 senior citizens, also half male and half female, who lived in a retirement community near Philadelphia. The community's "Reserve Fund" received $1.50 for each rater's participation. These respondents ranged in age from 65 to 87 years, with a mean age of 75.7 years. Respondents in both age groups were all Cau-

casian and predominantly from middle- to upper-middle-class background.

Relationships

Each person rated 14 relationships representing four levels of closeness (casual acquaintances, good friends, close relationship, and married pairs). At each degree of closeness except marriage, the two partners could be either both male, both female, or one male and one female. In the heterosexual pairs, the sex of the actor was also varied. Thus each rater considered eight heterosexual and six same-sex relationships.

The questionnaire first introduced the rater to four degrees of relatedness. Each pair relationship was pictured as two circles, varying in their degree of "intersection" (Levinger & Snoek, 1972) from very small to substantial. They were described as follows: (a) *casual acquaintances*—two people who feel friendly toward each other; the partners have many other relationships like this one; (b) *good friends*—two people who care about each other; each person has several other relationships like this one; (c) *close relationship*—two people who care about each other very much; the partners have no other relationship like this one; and (d) *married partners*—two people who care about each other very much; the partners have no other relationship like this one; they have made their relationship permanent.

Each rater received a booklet with the 14 relationships placed in a different random order. For each pairing, the relationship was described and the sex of each partner indicated, with the first person in each pair designated as the actor.

Behaviors

The 30 items used in this study (see Table 1) were selected from an initial list of 50 items to represent overt actions in the categories of joint activity, self-disclosure, other-enhancement, other-disparagement, norm regulation, and physical contact (positive and negative). The items chosen represented both physical activity and emotional expression, both verbal and nonverbal acts, and both positive and negative behaviors. A preliminary study showed that these items discriminated among the four degrees of closeness and covered a range of activities appropriate for most social relationships.

Choices of behaviors were guided by several criteria: (a) The behaviors were selected to represent specific acts, not abstractions such as many of the verbs in Osgood's (1970) study, nor behavioral intentions. (b) Items were to represent initiatory actions, since reactive behaviors would depend on their context. (c) Behaviors were to be applicable to all possible relationships; except for "making love," none of the items appeared likely to seem improper for same-sex pairs but proper for cross-sex ones.

Each behavior was rated on a 10-point scale ranging from 0 (not at all likely—i.e., would occur in 0%–10% of all relationships of the kind rated) to 9 (extremely likely—i.e., would occur in 90%–100% of all relationships of the kind rated).

The 30 items were presented 10 to a page, with 3 pages per relationship. The order of the three pages was randomly varied across the 14 pairings, so that no two respondents made their ratings in exactly the same order.[1]

A note on the rater's time perspective. While the young raters judged relationships among today's 22-year-olds, their contemporaries, older raters were asked to recall behavior norms of about 50 years ago. Although judgments of their own contemporaries seemed more meaningful than if senior citizens were to express norms about young pairs today, this procedure introduced a difficulty for interpreting the data: The older raters' judgments depended on their recollections. This difference will be discussed further at the end of the article.

Results

Our findings will be presented as follows: First we will consider the implicit dimensions of closeness that seem to underlie the respondents' ratings; the relationships judged by each group of raters will be plotted into a two-dimensional space. Next we will look at mean expected probabilities for the average social behavior across relationships and across generations. Following that, we will examine variations in different kinds of behaviors, using the results of a five-factor analysis of variance. Finally, we will focus intensively on intergenerational differences in expectations for appropriate interaction in close pairs.

Dimensions for Distinguishing Among the Relationships

In order to compare the 14 relationships simultaneously across several dimensions, a multidimensional scaling analysis was performed on the ratings of each age group. Individual Differences Scaling (INDSCAL), developed by Carroll and Chang (1970), was

[1] A preliminary study, using 50 behavior items, was carried out with two other groups of 40 young and 40 old respondents (Lacey, 1977). Because of a design error, its results could not be submitted to multidimensional scaling analyses. The methods of that study otherwise parallel the present ones, and its results will be referred to wherever they are relevant to the present findings.

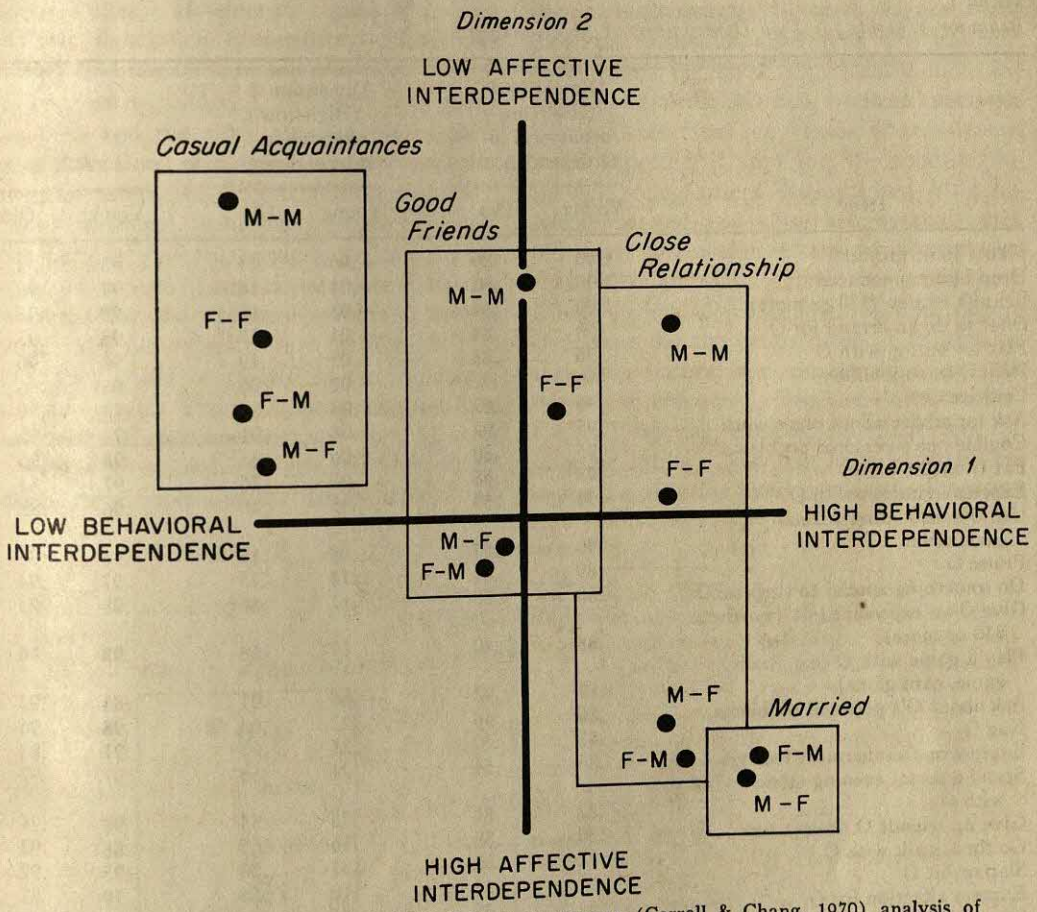

Figure 1. Relationship dimensions derived from an INDSCAL (Carroll & Chang, 1970) analysis of the younger respondents' behavior ratings. (For each pair, the first letter denotes the actor, the second the target of the action. M = male; F = female.)

used; the statistical program allows simultaneous analyses of all 14 relationships and provides unique solutions without any rotation of axes.[2] The INDSCAL analyses produced a relationship space for each group of raters with several dimensions and weights on each dimension for each behavior, to reflect the importance of each item for contributing to that dimension.[3] Distances between points in the space indicated the perceived dissimilarity among relationships. The analyses showed that a one-dimensional solution accounted for 81% and 74% of the variance for the young and the old raters, respectively; a two-dimensional solution accounted for 89% and 83%, respectively; and a three-dimensional solution accounted for 91% and 86% of the variance for the young and old raters, respectively. Since the further increment from two to three dimensions had little meaning, the two-dimensional solution was used.

Figure 1 shows the 14 relationships judged

[2] Input for the INDSCAL analyses was the dissimilarity matrix for each relationship, derived from the following formula:

$$\delta_{jk(s)} = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(x_{ijs} - x_{iks})^2},$$

where δ_{jk} is the dissimilarity between relationships; x_{ijs} and x_{iks} are Subject i's ratings of Relationships j and k on Behavior s; and N is the number of subjects who rated the relationships on Scale s (see also Wish, Deutsch, & Kaplan, 1976, p. 411).

[3] These dimension weights are analogous to partial correlations, whereas the R values (see last column of Table 1) are analogous to multiple correlations.

Table 1
Behavior Weights for Two Dimensions of Relationships

Item[a]	Dimension 1 (High–low behavioral interdependence)		Dimension 2 (High–low affective interdependence)		*R*	
	Young	Old	Young	Old	Young	Old
Plan a joint project	1.00	.89	−.06	.15	.98	.98

Percentage of variance for two-dimensional solution					89	83

Note. O = the other.
[a] Items are listed according to decreasing weights for the young raters on Dimension 1.

by the young raters. They are arrayed on two dimensions. Dimension 1, accounting for the largest amount of variance, can be interpreted as a pair's degree of behavioral interdependence. Most of the 30 behaviors had high weights on this dimension (e.g., planning a joint project, helping the other learn a hobby, or asking for advice about work; see Table 1). Casual pairs were rated lowest on behavioral interdependence and married pairs highest, with good friends and close relationships intermediate.

Dimension 2 refers to the pair's degree of affective interdependence. This dimension is characterized by physical contact—by behaviors such as making love, hugging, holding hands, or showing affection (and, for the older raters, by self-disclosure to and criticism

of the other). Heterosexual pairs were considered highest on Dimension 2, male pairs lowest, and female pairs intermediate.

The correspondence between the young sample's and the older sample's use of these two dimensions was estimated by correlating their respective coordinate positions in their two-dimensional solutions. Product-moment correlations were extremely high for both Dimension 1 (.969) and Dimension 2 (.936). Accordingly, the separate solutions for the young and old raters were rotated slightly so that they could be plotted in the same relationship space. Figure 2 shows the resulting intergenerational comparison.

While behavioral and affective interdependence were important for describing the ratings of both samples of raters, Figure 2 also indicates important differences. For example, older raters perceived significantly more behavioral interdependence between same-sex than between cross-sex friends, whereas young raters expected, if anything, the opposite. Although young raters distinguished little between married and close heterosexual pairs, old raters distinguished considerably between these intimate pairs; they also rated good friends as less interdependent on both dimensions than did the young raters. Furthermore, the older raters saw relationships at each degree of contact as less affectively differentiated by sex composition than did the younger raters. This may have occurred because the affective interdependence dimension

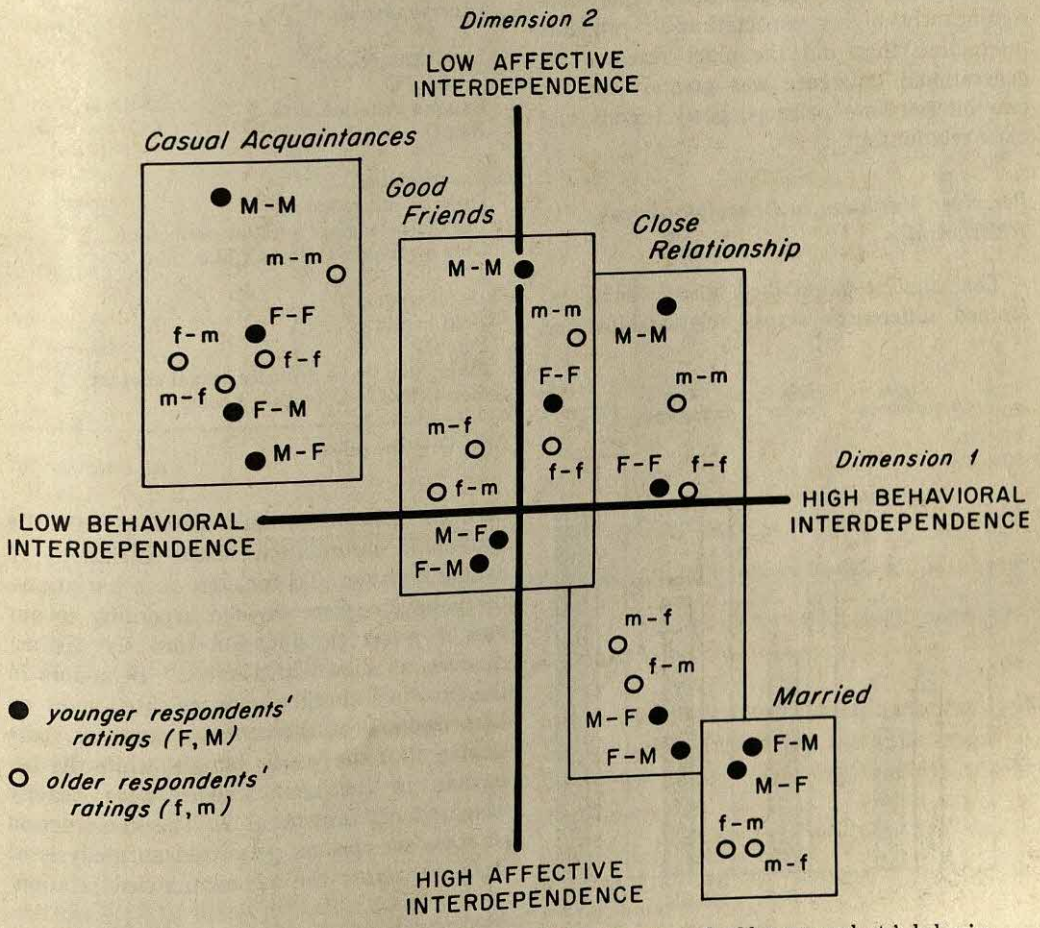

Figure 2. Relationship dimensions derived from both younger and older respondents' behavior ratings. (For each pair, the first letter denotes the actor, the second the target of the action. M, m = male; F, f = female.)

was largely based on physical contact behaviors; the older participants rated such contact quite improbable across all unmarried relationships, whereas the younger ones' ratings varied from low to very high.

Behavior Probabilities Across Relationships and Generations

The multidimensional analysis does not in itself reveal absolute percentage differences between the younger and the older samples, or among the relationships. Figure 3 shows such mean differences. It shows the extent to which probability of interaction was perceived to increase with relationship closeness. At each degree of closeness, and for almost all behaviors, the younger raters reported a significantly higher expectation of probable interaction than did the older raters. This generational difference was greatest for the two intermediate pairings, good friends and close relationship.

Perceived Variation in Behaviors Across Relationships

The analyses described above have examined differences across relationships and between generations but have given little systematic information about variations in dyadic behavior. To consider such variations, the behaviors were divided according to our own *a priori* classification into six distinct clusters, as shown in Table 2.[4] Behaviors in the first five clusters were weighted most on Dimension 1 of the INDSCAL analysis, particularly for the young sample, while the behaviors in the sixth cluster were heavily weighted on Dimension 2. The construction of these six clusters permitted an analysis of variance across the 12 nonmarried relation-

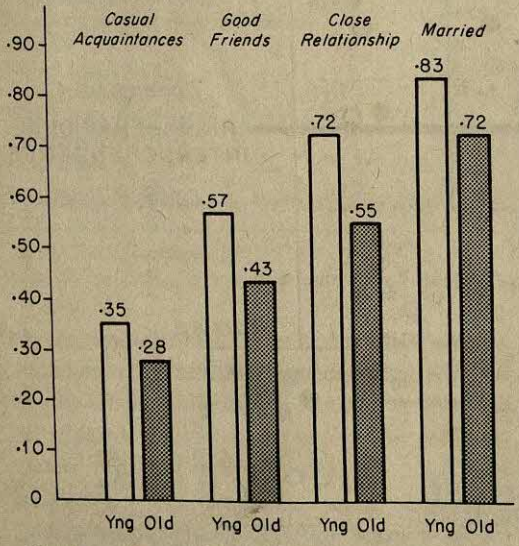

Figure 3. Mean probabilities of interaction across four degrees of closeness as estimated by both younger and older raters.

Table 2
Six Behavior Clusters Used in the Analysis of Variance

Social contact
Play game with O (e.g., ball game, card game)
Ask for advice about one's work
Help O learn a hobby
Offer to do an errand for O
Plan an outing with O
Go for a walk with O
Self-disclosure
Confide one's personal problems
Ask about O's personal problems
Express one's innermost feelings
Other-enhancement
Praise O
Pat O on back
Do something special to surprise O
Express affection for O
Other-disparagement
Criticize O
Express irritation with O
Nag O
Norm regulation
Drop by unannounced
Use O's belongings without permission
Give up friends O doesn't like
Physical contact
Hold hands
Hug O
Make love (have intimate sexual contact)
Stand close to O (within 1 foot)

Note. O = the other.

[4] Seven items were omitted from this analysis of variance across categories because they did not clearly fit into any of the six behavior categories.

Note. For each pair, the first letter denotes the actor; the second, the target of the action. M = male; F = female.

[a] Any discrepancy between the probabilities reported in this column and in Figure 1 is due to the different number of items on which the means are based.

[b] Probabilities for the married partners are shown here, even though the married relationship was not included in the analysis of variance.

ships. The one between-group factor was the raters' age (young or old);[5] the four within-subjects factors were the closeness of the relationship (casual acquaintances, good friends, close relationship), sex composition (same sex, cross-sex), sex of actor (male, female), and the type of behavior (joint activity, self-disclosure, other-enhancement, other-disparagement, norm regulation, and positive physical contact). Each of these variables exerted a statistically significant effect on the ratings.[6] Table 3 depicts the mean perceived probabilities across all four within-subjects variables;

[5] Sex of rater was omitted from this analysis, since previous analyses had shown no significant main effect ($p > .10$) nor any significant interaction effects of the raters' sex.

[6] Parallel findings were obtained for the data collected in the preliminary study, which also had included many additional behaviors.

Table 4
Mean Probabilities for Six Behavior Clusters Across Three Levels of Closeness

Cross-sex	.80	.69	.76	.47	.51	.73	.66

for the sake of simplicity, it disregards generational differences, which will be considered later.

Effects of closeness. As anticipated, interaction was expected to increase directly with the increasing closeness of the partners; mean probabilities were 28% for casual acquaintances, 48% for good friends, and 63% for the close relationship. These differences were highly significant statistically, $F(2, 156) = 463.62$, $p < .0001$.

The six clusters of behavior items differed significantly, $F(5, 390) = 229.64$, $p < .001$. For some clusters, increases in likelihood across degrees of relationship closeness were steep and others were gradual; some began from a low baseline and others from a moderate baseline (see Table 3). Joint activity and other-enhancement were perceived to be moderately probable (49% and 35%, respectively) among casual acquaintances and to rise high (87% and 86%, respectively) for the married pair; most other behaviors were considered to be improbable between casual acquaintances (less than 25%). Self-disclosure and physical contact were perceived to rise steeply (to 83% and 90%, respectively) as closeness increased. The behaviors subsumed under norm regulation and other-disparagement leveled off at a lower ceiling (68% and 61%, respectively).

Sex composition. The sex composition of a relationship was also significantly associated with the expected probability of behavior, $F(1, 78) = 23.76$, $p < .0001$. Overall, cross-sex pairs were expected to interact somewhat more than same-sex pairs (see Table 3). That effect was conditioned, however, both by the degree of closeness (there was no such difference for good friends) and by the sex of the same-sex pairs (female–female pairs were believed more likely than male–male pairs to initiate interaction across almost all sorts of behavior). Further, while cross-sex means tended to be about the same regardless of who was the actor, in same-sex dyads females were expected to interact more than were males (see row totals in Table 3).

How did same-sex and cross-sex pairs differ in regard to particular behavior clusters? Considering first the rather neutral behaviors classed under "joint activity," interaction was expected to be somewhat greater in same-sex pairs—for good friends, significantly so (see Table 4). Regarding self-disclosure, same-sex and cross-sex means were overall about equal, but same-sex good friends and cross-sex close ones were believed to disclose the most. Other-enhancement was believed to be significantly higher between cross-sex partners, but this difference was entirely due to the low means for male–male dyads. Other-disparagement, in contrast, was expected to be higher between same-sex than cross-sex partners, primarily for good friends. The cluster of norm regulation behaviors (i.e., dropping by unannounced, borrowing belongings and giving up friends the other does not like) was believed more characteristic of same-sex than of cross-sex interaction, but mainly for the good

friends. Finally, as hypothesized, the largest same- versus cross-sex difference, at every level of closeness, occurred for behaviors associated with physical contact.

Other notable sex differences may be seen in comparing the means for male and female same-sex dyads in Table 5. Overall, interaction was estimated as higher in the female pairs at each level of closeness; but these differences were due almost entirely to three of the six behavior clusters: to greater self-disclosure, other-enhancement, and physical affection between females. There were insignificant differences between male and female pairs with regard to expected joint activity, other-disparagement, or norm regulation.

Sex of actor. The analysis of variance located a significant effect of the actor's sex, $F(1, 78) = 14.19$, $p < .0001$, but only in the heterosexual pairs is it meaningful to consider male versus female actor differences. Turning to the data on cross-sex pairs in Table 5, one can examine differences in behavioral interaction attributable to the sex of the actor. In general, the male was expected to initiate more physical activity, ranging from working to playing games and making love, whereas the female partner was believed more likely to initiate verbal activity, such as giving praise or disclosing feelings.

Such male–female differences appeared to decrease with increasing pair closeness. The Total column of Table 3 shows that in the casual acquaintanceship, the male partner was believed more likely than the female partner to initiate all behaviors, particularly other-enhancement and physical contact. When the two persons are good friends or closer, however, the difference becomes negligible and is actually reversed in the marriage relationship. In other words, our respondents perceived it as more appropriate for male than for female members of casual relationships to initiate interaction, but in more intimate relationships, initiating an interchange was seen as equally appropriate for either sex.

Generational Differences

As shown above, the raters' generation strongly influenced their expectations of appropriate behavior in various relationships, $F(1, 78) = 45.40$, $p < .0001$. Altogether, older raters expected less interaction between partners than did young raters (44% vs. 58%). We now consider additional differences between groups both for relationships and for behaviors. We also explore within-group variations in behavioral expectation.

Relationship differences. Although older raters expected less interaction than did young raters, this difference was largest for the pairs intermediate in closeness (i.e., for the good friends and close relationship; see Figure 3). To assess these differences between the young and the old sample's mean ratings, a set of 420 significance tests was computed—one for each of the 14 relationships, for each of the 30 behaviors. About 35% of these comparisons were significant (by t test) at the .003 level or higher—the appropriate significance level for the conservative Bonferroni

Table 5
Mean Probabilities for 6 Behavior Clusters for 12 Relationships Differing in Sex Composition

Relationship	Joint activity	Self-disclosure	Other-enhancement	Other-disparagement	Norm regulation	Physical contact	Total
Same sex

Cross-sex							
M–F	.67	.45	.58	.35	.34	.51	.48
F–M	.65	.46	.55	.35	.32	.48	.47

Note. For each pair, the first letter denotes the actor; the second, the target of the action. M = male; F = female.

Table 6
Mean Probabilities for Six Behavior Clusters Estimated by Young and Old Raters

Group	Joint activity	Self-disclosure	Other-enhancement	Other-disparagement	Norm regulation	Physical contact	Total
Young	.73	.58	.65	.50	.46	.54	.58
Old	.66	.44	.54	.29	.34	.39	.44
Total *M*	.70	.51	.60	.39	.40	.47	.51
Young–Old difference	.07	.12	.11	.21	.12	.15	.14

t test comparison. These differences between the young and the old raters' means were significant for only 15% of the casual acquaintances and 27% of the married pair ratings. In contrast, the young–old mean differences were significant for 41% of the good friends and for 55% of the close relationship ratings.

Generational differences were more noticeable for ratings of cross-sex than of same-sex relationships (40% vs. 29% of the comparisons), and these differences were significant most frequently for female-initiated interaction in the female–male pair: 49% of these contrasts were significant compared to 32% for the male–female, 30% for the female–female, and 28% for the male–male pairs.

Behavior differences. Although the young raters consistently perceived more interaction across the 14 relationships than did the old raters, these differences varied according to the type of behavior. Table 6 shows the mean probabilities for the six behavior clusters. (The following discussion utilizes other data for individual items and relationships that are not presented here.)

Intergenerational differences were least evident in expectations about activity-centered interaction; the data indicate little change over the years, except for today's females being thought more likely than their counterparts of 50 years ago to initiate interaction with their close male partner.

The largest difference occurred in the older generation's perceptions of greater inhibition in regard to criticizing another; today's raters saw as more permissible the disparagement of the partner, including such actions as nagging, criticizing, and expressing irritation.

Generational differences were also quite large for disclosing feelings to another. For each relationship other than the casual acquaintanceship, today's 22-year-olds were perceived as significantly more likely than those of 50 years ago to express their feelings, to ask about a partner's personal problems, and to confide their own personal problems.

Other-enhancement also was perceived as more likely between today's than yesterday's 22-year-olds. Particularly in the close relationship, friends today were perceived as more likely to praise the other and to express affection; especially, it was indicated that females are freer to acknowledge affection toward males than they were two generations ago.

Physical contact was another noticeable area of generational difference. Heterosexual partners today were believed far more likely to pat one another on the back, to hug, or to make love; and such interactions today were considered nearly as likely to be initiated by females as by males. Such differences were extended to same-sex pairings; young raters believed it significantly more likely that both female and male pairs would express some physical affection for each other. (Another finding, concerning negative physical contact behaviors not included in the six major clusters—for instance, slapping or hitting a partner—was that they, too, were perceived as more likely in today's relationships.) The expression of all sorts of feelings appears more permissible today than yesterday.

Within-group age variations. After finding such pervasive differences between the young and the old group of raters, it became important to ask whether similar trends might be detected *within* a single age group. If younger raters *within* an age group were

consistently found to expect more interaction than older raters in that *same* group, such a finding would strengthen the validity of the between-groups comparisons.

The ages of the college raters were very homogeneous, with a range of only 8 years, but among the senior citizens the age range was 22 years (from 65 to 87). Therefore we expected to find no meaningful correlations within the young group but did hope to find negative Age × Probability correlations within the old sample. Within each age group of raters, and for each of the 14 relationships, we computed correlations between the raters' ages and their probability ratings on a subsample of six behaviors that had earlier shown significant between-groups differences.[7]

For the young group, as was expected, no overall trend emerged. For the older age group, 95% of the correlations were negative; 21% of them were significant at the 5% level. In other words, 65-year-old raters describing relationships of 45 years ago tended to recall a higher probability of interaction than did 75- or 85-year-old raters describing pairs of 55 or 65 years ago. This correlational finding gives strong confirmation to the age effects found in the between-groups comparisons.[8]

Discussion

It was found that variations in the closeness and sex composition of pair relationships exerted strong effects on normative expectations of interaction across a wide variety of dyadic behaviors. Those findings applied both to college students judging interaction between today's 22-year-olds and to senior citizens judging interaction between 22-year-olds when they themselves were young, although there also were important intergenerational differences. There were no significant effects of the judges' own sex in either of the two samples. After reviewing such effects and discussing their implications, we will assess the usefulness of this method for comparative research on close relationships.

Effects of Closeness

As a relationship moves from casual to close, its interaction probabilities were perceived to increase correspondingly. Behaviors pertaining to touching or disclosing oneself to the partner were believed to be most affected by increases in closeness, whereas less intimate joint activities, such as planning a joint project or doing an errand for the other, were believed to be least affected. These findings confirm earlier theoretical proposals about the meaning of a growing person–other "intersection" (Levinger, 1974; Levinger & Snoek, 1972). With the exception of fairly neutral task-oriented activity or of strongly affective sexual activity, the closeness of a relationship exerted an increasing, monotonic effect on perceived probabilities of interaction. Nonetheless, the relationships of good friends were perceived to be much more similar to those of close friends than to those of casual friends, as was indicated by their location on Dimension 1 of Figures 1 and 2 and by the means shown in Figure 3. This finding parallels those obtained in Mack's study of perceived behaviors in heterosexual couples (cited in Levinger, 1974) and in Stambul's (1975) retrospective investigation of stages in the courtships of premarital pairs; Stambul found that the stage of serious dating was much more similar to the stage of engagement than to that of casual dating.

The two age groups were largely parallel in these effects but also showed some differences. At each level of closeness, older respondents rated the interaction probabilities significantly lower than did the younger respondents. Greater young–old contrasts occurred for the relationships intermediate in closeness (good friends and close relationship) than for those at the extremes of casualness (casual acquaintances) and closeness (married); such contrasts were noted particularly in the older respondents' lower rat-

---

[7] For this analysis we selected a sample of six behaviors from different clusters that had shown larger intergenerational differences: stand close to the other, ask about the other's personal problems, hug the other, criticize the other, confide one's personal problems, and express irritation with the other.

[8] In the preliminary study, too, the older sample of raters had shown significant negative correlations between raters' ages and the behavior probabilities they estimated for the pairs of friends.

ings of physical contact and other-disparagement.

Effects of Sex Composition

Norms for cross-sex pairs were seen to differ from those for same-sex pairs, but those for female and male same-sex pairs were perceived as even more dissimilar. The sex of the actor, too, had an effect on ratings of behavioral expectations.

Cross-sex versus same-sex differences. The largest differences between cross-sex and same-sex pairs occurred for the close relationship. At this level of closeness, cross-sex pairs were perceived as more likely than same-sex pairs to engage in self-disclosure, other-enhancement, and physical contact. In contrast, for good friends, same-sex pairs were seen as more likely to interact than were cross-sex ones (except for having physical contact).

Male–male versus female–female differences. The effect of sex composition is revealed further in the ratings of interaction in same-sex pairs. Female pairs were expected to engage in greater self-disclosure, other-enhancement, and physical contact than were male pairs. These expectations parallel findings from other studies. Previous research has found that female friends do indeed disclose more intimate details about their lives than do male friends (Jourard, 1971), report greater emotional involvement in their friendships (Rubin, 1973; Purdy, Note 3), have longer interactions (Wheeler & Nezlek, 1977), and do things together more spontaneously (Booth, 1972). Weiss and Lowenthal (1975) found that males emphasize sharing activities and interests more than do females, whereas females emphasize the importance of warm supportiveness.

Pleck (1975) has suggested that women's friendships are traditionally intimate, whereas men's friendships are more sociable than intimate—a distinction he derived from an analogy to Lewin's (1948) cross-cultural analysis of German versus American relationships. Our data support Pleck's suggestion. The multidimensional analysis shows that at each degree of closeness, most sorts of interactions were expected to be lowest for same-sex male pairs, intermediate for female pairs, and highest for cross-sex pairs. Males, then, are believed to obtain emotional gratification from cross-sex relationships, whereas females are intimate with friends of either sex. This inequality, also alluded to in studies of adolescent friendships by Douvan and Adelson (1966) and Komarovsky (1976), implies that males are more emotionally dependent than females on their heterosexual relationships, in that they have learned to minimize the emotional value of their same-sex friendship.

Sex of actor. Differences between male and female actors were in accord with tradition. Males were believed more likely to initiate overt physical activities, such as playing games, and females to initiate verbal interaction, but such sex differences were expected to diminish with the deepening of a relationship.

This finding accords well with independent empirical research. For example, in a study of discussions in heterosexual pairs, Heiss (1962) found that among "casual daters," males were more task oriented and females more social–emotional, but "committed" partners differed little along such traditional lines. Furthermore, two studies of married couples (Levinger, 1964; Raush, Barry, Hertel, & Swain, 1974) found little difference between male and female spouses in their dyadic social–emotional behavior. In other words, increasing closeness is associated with a reduction of sex typing.

Variations in Behavior

Multivariate analyses indicated the presence of a primary dimension indicating general activity or behavioral interdependence and of a secondary dimension indicating intimacy or affective interdependence. The first dimension means that to the extent that partners share one type of interaction, they are judged likely to engage also in other kinds of exchanges. A wide range of behaviors was believed to become more probable as relationships become closer.

The second dimension refers to behaviors that are associated with affection; they include physical touch, hugging, making love,

and expressing affection. For the older raters, negative remarks to the partner as well as strongly positive disclosures were also a component of this "affectivity" dimension.

The present study was designed to compare relationships only with regard to variations in their expected behavior; the two orthogonal dimensions obtained in the present study, therefore, are undoubtedly influenced by the selection of the particular behaviors. Nonetheless, our two dimensions of behavioral and affective interdependence appear generally meaningful. Behavioral interdependence refers to the sheer frequency or likelihood of joint action across a wide variety of behaviors. Affective interdependence, in contrast, refers to the frequency of emotional expression toward the other.

Selection of behaviors in the present study. Previous studies compared relationships with regard to traits (e.g., Wish et al., 1976) or interpersonal feelings (DeSoto & Kuethe, 1959), but in this study we focused on overt action. In doing so, we found great difficulty in selecting a satisfactory sample of interpersonal behaviors, both in getting lists of pair behaviors from samples of naive judges and in constructing such lists ourselves. The list of 30 behaviors was derived largely from the suggestions of college students and other younger persons. It may have been less representative of behaviors that older respondents would have considered important, even though they were able to respond to these items.

Our preliminary study of 50 behaviors had included equal numbers of associative and dissociative acts, but raters had found negative acts to be less clearly interpretable. Because of that ambiguity, and also because the many negative (unlikely) acts may have lowered rater motivation to consider relationships realistically, the main study included only seven negative behavior items. These points are mentioned in the hope that future investigators will arrive at a more elegant sample of behavior items.

Effects of the Raters' Generation

Older raters, recalling the behavior of 22-year-old pairs when they themselves were that age, showed systematically different impressions of pair interaction from those of college-age raters. For almost all relationships and behaviors, old raters recalled significantly lower probabilities of interaction than did young raters; the differences were particularly pronounced for the good friends and for the close relationship. Today's pairs were expected to be more expressive, to do more things together, to reveal a greater proportion of their positive and negative feelings, and to have more physical contact. Such young–old differences were least for superficial activities (e.g., playing games or spending a social evening together) and were less marked for the casual and the married pairs. Parallel young–old differences were found in an internal analysis of the two samples of older raters; for a set of representative behaviors, the raters' ages and their estimates of interaction probabilities were inversely correlated.

One other age difference pertained to the heterosexual relationships. Old raters made a significantly greater distinction between the behaviors of female and male actors. Yesterday's female was perceived as less equal to her male partner than is today's. The generational difference in this study referred particularly to the female's initiation of physical contact and of joint activity.

Limitations of the young–old comparison. It was noted earlier that these data refer to raters' *perceptions* of typical relationships. We do not know how nearly such ratings correspond to "reality." It is possible, for example, that older raters, who had to think back 50 years to recall their own and other people's friendly relationships when they were young, would have distorted their ratings of interaction in some systematic way. In other words, it is possible that yesterday's stereotypes were less accurate than today's. It is also likely that 50 or so years ago, there were in fact fewer instances of "close" heterosexual relationships short of marriage between 22-year-olds; our questionnaire did not ask respondents to indicate the expected frequency of such relationships, but that fact may have influenced these results. Furthermore, while most of the older raters had a middle-class, fairly well educated socioeconomic back-

ground, it is impossible to make a clear-cut socioeconomic comparison between two age groups at such very different stages in their lives.

Nonetheless, our correlational results do support the idea of growing trends toward more openness and expression. Despite the necessary absence of customary experimental controls, our results do confirm intuitive analyses (Stegner, 1971) and documentary evidence (Gadlin, 1977; Murstein, 1974) of historical changes in intimate relationships.

Comparative Assessment of Relationships

The present study has examined a technique for collecting and analyzing "snapshots" of different stages of interpersonal relationships, beginning with casual acquaintanceship and moving through friendship to very close relationship and marriage. Without tracking the interaction of actual pairs over time, it enables one to gather systematic data about people's implicit theories about the conduct and the development of relationships.

Considered alone, the approach yields summaries of people's subjective impressions that permit intergroup comparisons. Considered in conjunction with other more objective observations, a useful overall picture may emerge. Despite its susceptibility to possible distortion, the present procedure permitted a systematic intergenerational comparison that can be integrated with documentary data. Furthermore, a variety of other empirical studies (see Chaikin & Derlega, 1974; Huston & Levinger, 1978; Levinger, 1974; Morton, 1978) have shown that relations at superficial levels are oriented largely toward doing a particular activity with any other person; at deeper levels they become increasingly oriented toward doing any activity with a particular other. The present research tends to confirm this.

Our survey method provides a mapping of people's beliefs about behavior—a means of comparing differences across relationships that vary in depth and sex composition. A weakness in earlier relationship research has been its lack of system, its tendency to study some variables in one kind of relationship (e.g., marriage) and quite other variables for another relationship (e.g., same-sex friendship or first impressions of an acquaintance; Huston & Levinger, 1978). The present method may encourage better comparative research. It may be useful for historical and cross-cultural comparisons and thus may facilitate the recognition that the meaning of interpersonal behavior is embedded in its sociocultural context.

Evaluation of Outcome Improvement Resulting From Threats and Appeals

André deCarufel

University of North Carolina at Chapel Hill

In a simulated industrial setting, subjects performed a clerical task, believing that their pay was being determined by a peer allocator. After being treated inequitably, subjects were able either to threaten the (fictitious) allocator or appeal to fairness principles, or they had no say ("mute" condition). During a second series of pay periods, subjects' pay either remained constant, improved such that they and the allocator received equal shares, or improved such that subjects received *more* than the allocator ("compensation" condition). The *total* pay was identical in all conditions and created a context of overall inequity. Increased satisfaction and perceived fairness were observed with improved outcomes in both the mute and the threat conditions. In the appeal conditions, satisfaction and perceived fairness were highest in the equality cell. These results are interpreted in terms of relative deprivation. Implications for responses of recipients in ameliorative social programs are presented.

The concept of *relative deprivation* was introduced by Stouffer et al. (1949) to account for "paradoxical" observations in their studies of the American soldier during World War II. Theoretical development in this area has continued to the present day (e.g., Crosby, 1976; Davis, 1959; Gurr, 1970; Runciman, 1966). In all of these formulations, felt injustice has been characterized by a discrepancy between the individual's outcomes and experiences and those that he or she feels are deserved. A similar rationale is evident in recent formulations of equity theory (Adams, 1965; Berkowitz & Walster, 1976), distributive justice (Homans, 1974), and justice theory (Lerner, 1977). The consequences of injustice involve psychological states roughly equivalent to anger and dissatisfaction. These states are hypothesized to motivate behavioral attempts to remedy the injustice, and there exists a strong historical connection between these states and conflict, violence, and revolution (c.f. Davies, 1962; Sears & McConahay, 1973). Though the results of attempts to rectify injustice have often been in the direction of objective outcome improvement, the satisfaction associated with these increases in outcome level is sometimes temporary. This is because the subjective standard by which outcome levels are evaluated may also rise when outcomes improve, a process referred to as the "hedonic treadmill" by Brickman and Campbell (1971).

The improvement itself may be a source of rising expectations, by making salient valued end states to which the individual feels entitled. To the extent that these rising, legitimate expectations are violated by improvements that fail to rise at the same rate or occur in a capricious manner, a second condition for dissatisfaction is present. Finally, if the violation occurs by illegitimate means, as in the case in which an allocator of outcomes is perceived to be intentionally holding back the rate or extent of improvement, the experience of injustice should be acute. Under these conditions, outcome improvement may be predicted to lead to dissatisfaction and hostility rather than to satisfaction (cf. Brown, in Brown & Herrnstein, 1976; Crosby, 1976).

Research Evidence

Anecdotal evidence for this proposition abounds. For example, de Tocqueville observed that "evils which are patiently endured when they seem inevitable become intolerable when once the idea of escape from them is suggested" (quoted in Davies, 1962, p. 6). However, experimental evidence concerning the link between improvement and discontent is scarce. Thibaut (1950) found that disadvantaged parties who were successful in influencing the experimenter to allow them to perform the interesting tasks in an experimental game exhibited more hostility toward the formerly advantaged group than did those who were unsuccessful.

A recent $2 \times 2 \times 2$ experiment by Folger (1977) examined these issues more closely. He constructed a simulated industrial setting in which sixth-grade boys performed a clerical task and were paid over a series of trials by a (fictitious) manager. After an initial period of inequitable treatment, half the boys were allowed to express allocation desires to the manager ("voice" condition), whereas half were not ("mute" condition). During the remaining pay periods, the subjects' pay either improved or remained constant, and the final totals were either inequitable ($\frac{2}{3}$–$\frac{1}{3}$ in the manager's favor) or equitable ($\frac{1}{2}$–$\frac{1}{2}$). The results were that in the inequity half, improvement led to greater perceptions of fairness and lower requests for more pay in a bonus session than did no improvement when it was granted arbitrarily (mute condition), but the *reverse* was true in the voice conditions. In the equity half, perceived fairness was high in all of the cells. What could account for these data, particularly the pattern of means in the inequity half?

Folger suggested that the manager's positive response to the subject's expression of allocation desires (i.e., the improvement) represented an acknowledgment that the appeal was legitimate and created the expectation that fair allocations would follow. The inequity that remained in the final totals dashed these hopes in a particularly cruel fashion. From the subjects' perspective, the manager confirmed their right to higher pay and then blithely continued allocating for his own benefit. The negative response (no improvement) did not endow the appeal with this legitimacy and may even have represented a *denial* of subjects' right to more pay. This response undercut any basis for strong discontent. In the mute conditions, on the other hand, the allocations were experienced relative to those of the first set of pay periods. The improved outcomes were satisfying; the constant ones were not.

Rationale for the Experiment

The Folger (1977) account relies very heavily on the *nature* of the interchange between worker and manager. The "voice" was clearly an *appeal* to principles of fairness. Subjects filled out a "fair pay card" to communicate how they thought pay ought to be allocated. There are other possible interpretations, however, that are simpler in the sense that they suggest that voice per se may have produced the differing evaluations of the improvement in the mute and voice conditions. Discontent in the voice–improvement cell, relative to that in the mute–improvement cell, may have reflected a greater willingness on the part of these subjects to *express* their feelings ("expression hypothesis"). These subjects, after all, had already been encouraged once before by the experimenter to voice their discontent, whereas those in the mute conditions had not. Voice–improvement subjects may have thought the manager less fair because they attributed the improvement to the "external pressure" of their complaint, rather than to the manager's spontaneous desire to increase their outcomes ("attribution hypothesis"; cf. Kelley, 1971). Finally, voice–improvement subjects may have viewed the manager as a bully who "acted tough" in the first few pay periods but who was easily cowed when they confronted him, leading to a lowered evaluation of him and his actions ("derogation hypothesis").

A direct way to disentangle these possibilities is to manipulate the nature of the opportunity for expression available to subjects. If it is voice per se that produces the effect, then allocations following from differ-

ent kinds of voice should be evaluated similarly. If the effect depends on the arousal of fairness principles, then communications to the allocator not involving issues of fairness should not result in evaluations of the subsequent allocations similar to those that do. This raises the general issue of the impact of the *procedures* by which improvements are wrested from advantaged parties on how these "gains" are evaluated.

A particularly interesting type of voice, not involving fairness, is one in which the worker is able to threaten the allocator with dire consequences if the pay is not increased. Note that this maneuver involves expression, allows the improvement to be attributed to "external" pressure, and involves social influence. Thus, from the perspectives of the expression, attribution, and derogation hypotheses it is equivalent to an appeal to fairness. If, on the other hand, fairness principles are necessary for discontent, are there any grounds for predicting how an improvement following a threat to the allocator will be evaluated? The most straightforward prediction is that subjects will feel satisfied when their outcomes increase and dissatisfied when they do not. Satisfaction should be increased when the improved outcomes exceed those experienced previously; it should also be increased by the sense of mastery or control inherent in being able to force an apparently unwilling allocator to move away from the initial allocation pattern. It is also possible that subjects in these threat conditions would be *more* satisfied even than those in the *mute* conditions, where the increase comes about beyond the subjects' control (cf. Wortman & Brehm, 1975). Thus, this "threat" condition is one of special interest, because it could result in either satisfaction or dissatisfaction with the improvement.

To this point, outcome improvement has been discussed in general terms. It may be interesting, however, to examine how improvements of different objective magnitudes are experienced. Several alternatives are available to an allocator confronted by a request from a disadvantaged party for higher outcomes. One is to maintain the status quo (i.e., to continue the deprivation). With respect to improvement, the allocator could terminate the existing discrimination and begin allocating fairly from that point on ("equality"), or he or she could compensate the worker for the past inequity by giving the (former) victim a *better* than even share of the remaining allocations ("compensation"). It is clear that the magnitude of the improvement in the compensation case is objectively greater than that in the equality case, which in turn exceeds that in the constant case. The issue of what is fair compensation for victims of discrimination is a complex and explosive one, as the furor over allegations of "reverse discrimination" indicates. The focus here, however, is on how the victims themselves experience these improvements.

Hypotheses

The hypotheses will be presented in terms of how the improvements should be experienced within each level of the voice factor. It should be noted that *all* of the experimental conditions occurred within the context of overall inequity, since it was in these conditions that Folger (1977) found his most interesting results.

In the *mute conditions*, where improvements are evaluated against initial allocations, satisfaction and perceived fairness should increase as the new outcome level exceeds the old (i.e., be greatest in the compensation case and least in the constant case). In the *appeal conditions*, this pattern should be *reversed*. If the constant allocations represent a denial of the worker's right to higher pay, as Folger suggested, there should be little, if any, discontent when no improvement is forthcoming. In the improvement cases, the positive response should increase the perceived legitimacy of the subject's claim. Further, it is likely that the magnitude of the improvement itself should affect subjects' perception of their own deservingness. The further subjects are taken in the direction of a complete restoration of equity (where Folger found high satisfaction), the more they should expect it and feel entitled to it. These subjects should also feel most chagrined when this standard is not reached.

In a sense, it is like a "goal gradient," where they are taken ever closer to the goal before it is snatched away. Thus, satisfaction and perceived fairness should be *lowest* in the compensation case and greatest in the constant case.

The *threat conditions* could go either way. With no fairness principles involved, it is likely that the improvements would be experienced as increasingly satisfying as they exceed the initial outcome level. Further, the larger the increase that had been forced from the unwilling allocator, the more control or mastery of the situation subjects should feel, which should also increase their satisfaction. On the other hand, the expression, attribution, and derogation hypotheses would predict a pattern similar to that described above for the appeal conditions, since the increase in both cases resulted from "voice."

These predictions suggest a Voice × Improvement interaction. A 3 × 3 experiment crossing outcome improvement (constant, equality, compensation) and opportunity for expression (mute, threat, appeal) was conducted to examine these issues.

Method

Participants

Ninety-seven persons (63 females, 34 males) were recruited via sign-up sheets posted around the University of North Carolina at Chapel Hill. The experimenter scheduled each person by phone. Subjects were run two at a time, but since interaction between them was minimal, the individual was used as the unit of analysis. Five females and two males turned out to be "professional subjects" who attended any experiment involving payment. These subjects expressed some suspicion about the identity of the allocator. Their data were excluded from the reported analyses. The remaining 58 females and 32 males were randomly assigned to conditions until there were 10 respondents per cell.

Procedure

Two subjects at a time reported for an experiment called "Organizational Behavior" and were immediately ushered into separate rooms, which were linked to the experimenter's control room via an intercom system and a set of signal lights. The experimenter began by explaining that the focus of the experiment was on "factors affecting job satisfaction and performance." Subjects were told that the organization in which they would be working would consist of two roles—worker and allocator.

At this point subjects were assigned to roles by the use of a series of signal lights. All subjects discovered that they would be the worker and assumed that the other subject would be the allocator. In fact, the role of allocator was played by the experimenter. Each subject was aware of the sex of the allocator, but there was no systematic relation between experimental condition and sex of subject or the perceived sex of the allocator. The experimenter visited each subject and gave him or her a "worker's folder" containing experimental materials.

The experimenter returned to the control room and specified the duties of the two roles. The worker was told that he or she would perform a clerical task—transcribing numbers set up in the form of business transactions from a computer printout onto a work sheet. The number of items transcribed was to be used as a measure of productivity. Subjects were told that they would be paid by the allocator over a series of 10 pay periods, each lasting 1 minute. The allocator was to receive 24¢ in each pay period from the experimenter and would then divide up this sum between him- or herself and the worker. The experimenter indicated that he would announce the allocator's pay decisions after each pay period. Subjects were asked to write down these allocations on the payment record card in their folders. Subjects were also told that the allocator would check the worker's performance, but would only be able to do so at the end of the final pay period. In order to make the experimental situation more plausible, the experimenter indicated that this phase of the study was concerned with the degree of contact among organization members. They were told that this was the minimal contact condition, which accounted for their being in separate rooms and the allocator dividing up the pay at each pay period despite only being able to check the worker's performance at the end.

At this point, the experimenter visited each subject and answered questions about the procedure. Subjects were asked to fill out a fair pay card that asked what they thought would be a fair way for the allocator to divide up the pay.

The experimenter then announced that the first series of pay periods was about to begin and that subjects should begin their tasks. At 1-minute intervals, the experimenter informed them of the allocations. During this first series, the allocations were consistently unfair to the worker. After Pay Period 5, subjects were asked to total up the allocations on the payment record card and to fill out the first questionnaire.

The opportunity for expression manipulation was introduced at this point. In the mute conditions, the experimenter visited the subjects and asked whether they had any questions about the procedure. In the voice conditions, subjects were able to select a message for the experimenter to deliver to the allocator.

During the remaining five pay periods, the improvement manipulation was introduced. In the con-

stant conditions, the worker received the same outcomes as in the first half, whereas in both improvement conditions, his or her outcomes increased. In the equality conditions, the worker and allocator received equal shares, whereas in the overcompensation conditions, the allocator gave the worker *more* than he or she kept.

After Pay Period 10, the experimenter announced that the work session was over. He asked subjects to calculate their second-half and final allocation totals and to fill out the final questionnaire. When subjects were finished, they were led into a common room, fully debriefed, and paid a standard sum of $2 each for their participation.

Independent Variables

Two factors were manipulated: (a) opportunity for expression and (b) outcome improvement. The opportunity-for-expression factor was introduced between the two series of pay periods. The purpose of this manipulation was to vary the "tone" of the interchange with the allocator and cast the subsequent allocations in different lights. In the mute conditions, there was no opportunity for the subject to contact the allocator. The experimenter simply visited the subject's room and answered any questions the subject might have had. In both voice conditions, however, the subject was able to select one of three messages for the experimenter to pass to the allocator. One of these messages expressed satisfaction with the initial allocations, one suggested that the allocator should take *more* in the second half, and the third expressed dissatisfaction. Of course, it was expected that subjects would choose the third message.

This message went on to include further information specific to the threat or appeal conditions. In the threat conditions, the tone was clearly power-oriented and belligerent. Subjects believed that there would be a short bonus session following the 10th pay period, during which they would be able to bargain with the allocator. During this session, they were told they would be able to deliver loud bursts of noise into the allocator's headphones to back up their demands. The message that the subjects were able to choose emphasized this capability and stated that if their outcomes were not improved in the second half, they would use this weapon during the bonus session. The message concluded by demanding that the total shares of pay end up equal. Thus, this message did not mince words and had a distinctly "or else" quality about it.

In the appeal conditions, however, the message appealed to the allocator's sense of fairness and tried to convince him or her of the legitimacy of the request for a larger share. This message also suggested that the total shares ought to end up equal. To further enhance the legitimacy of the worker's request for more pay, the experimenter supposedly gave the allocator the subject's first questionnaire, which spelled out his or her dissatisfaction and felt injustice, and the subject's work sheet, which detailed the worker's performance during the first half. Thus, this message was based on an appeal to fairness and emphasized the worker's *entitlement* to higher pay.

The opportunity-for-expression factor was crossed factorially by a manipulation of outcome improvement. This manipulation was defined in terms of the amount allocated in the second half relative to that allocated in the first half. In the constant conditions, the allocator took two thirds of the available pay in both halves. The totals were $1.60 for the allocator and 80¢ for the worker. In the two improvement conditions, the final totals were identical, but the outcomes were distributed differently over the 10 pay periods. In the equality conditions, the allocator gave the worker an exactly even split (60¢–60¢) during the second half, whereas in the compensation conditions, the allocator gave the worker more (70¢–50¢) than he or she kept. Table 1 provides an array of the allocation schedules on a trial-by-trial basis for both worker and allocator.

Dependent Variables

The dependent variables were assessed at various points in the procedure. Before the pay periods, subjects filled out a fair pay card, which was a check on the perceived equity norm. Following Pay Period 5, subjects completed the first questionnaire, which assessed their satisfaction with, and perceptions of the fairness of, the initial allocations. Finally, at the conclusion of the work session, subjects completed the final questionnaire, which contained the main dependent variables. Subjects were asked how satisfied they were with their share of the pay in the second half ("satisfaction"), and how fairly they felt the allocator was dividing up the pay in the second half ("fairness"). They were also queried on their feelings about the *total* allocations, and the number of items they transcribed was tallied.

Results

Effectiveness of the Manipulations

The improvement manipulation was checked by asking subjects if their share of the pay changed from the first to the second half. Eighty-nine of the 90 subjects responded correctly ("no" in the constant conditions, "yes" in the improvement ones). They were also asked how much of a change there was in their share of the pay from the first to the second half (1 = none, 11 = very much). The means for the constant, equality, and compensation conditions were 1.2, 8.9, and 9.4, respectively, $F(2, 72) = 315.52$, $p < .001$.

The opportunity-for-expression manipula-

Table 1
Worker and Allocator Pay Schedules for the 10 Pay Periods

	Condition					
	Constant		Equality		Compensation	
Pay period	Worker	Allocator	Worker	Allocator	Worker	Allocator
			First half			
1	8	16	4	20	2	22
2	8	16	4	20	2	22
3	9	15	5	19	3	21
4	7	17	3	21	1	23
5	8	16	4	20	2	22
Sum	40	80	20	100	10	110
			Second half			
6	8	16	12	12	14	10
7	7	17	12	12	15	9
8	8	16	12	12	14	10
9	9	15	12	12	13	11
10	8	16	12	12	14	10
Sum	40	80	60	60	70	50
Total	80	160	80	160	80	160

Note. The amounts are in cents.

tion was checked by giving subjects a choice of four alternatives with which to sum up the content of the message sent to the allocator after Pay Period 5. The choices were (a) sending no message, (b) threatening possible retaliation, (c) appealing to fairness principles, and (d) other (specify). All 30 mute-condition subjects chose (a), 23 of the 30 threat-condition subjects chose (b), and 28 of the 30 appeal-condition subjects chose (c), $\chi^2(6) = 148.10$, $p < .001$.

Finally, subjects were asked how much influence they had been able to exert over the allocator to change the division of pay from the first to the second half (1 = none, 11 = very much). The Voice × Improvement interaction was significant, $F(4, 72) = 9.52$, $p < .01$. The mean for the four voice–improvement cells was 6.25, whereas the mean for the three mute cells and the two voice–constant cells was 1.16.

Evaluation of the Improvement

The analyses reported below were initially run using sex of subject as an additional factor to check on the generality of the effects. However, there were no significant effects involving this variable, so the data for male and female subjects were collapsed.

The first effect of interest is the significant improvement main effect: satisfaction, $F(2, 72) = 45.53$, $p < .001$, and fairness, $F(2, 72) = 63.56$, $p < .001$. The pattern of means indicated that in general, subjects were more satisfied and perceived the allocator to have been more fair when their outcomes improved in the second half than when they did not (see Table 2). The voice main effect was also significant for the satisfaction measure, $F(2, 72) = 5.20$, $p < .01$, but not for the fairness measure ($p > .35$).

These main effects were qualified by the hypothesized Voice × Improvement interaction: satisfaction, $F(4, 72) = 4.62$, $p < .01$, and fairness, $F(4, 72) = 2.43$, $p < .055$. The interaction was explored with Scheffé tests to specify more closely the nature of the effect. Only those tests achieving significance ($p < .05$) on *both* measures will be presented. Within both the mute and threat conditions,

Table 2
Means for the Evaluation-of-Improvement Items

	Opportunity for expression								
	Mute			Threat			Appeal		
Improvement	Constant	Equality	Compensation	Constant	Equality	Compensation	Constant	Equality	Compensation
Satisfaction measure	1.6	6.1	7.3	2.0	8.6	8.6	1.3	8.3	3.6
Fairness measure	1.5	8.6	8.0	1.9	8.0	6.9	1.5	9.3	4.4

Note. Higher numbers indicate higher satisfaction and fairness (1 = not at all, 11 = very much).

subjects felt more satisfied and more fairly treated when their outcomes improved than when they did not. The equality and compensation cells did not differ. Within the appeal condition, however, the improvement in the equality cell resulted in increased satisfaction and perceived fairness compared with the constant cell. The objectively larger improvement in the compensation cell did *not* produce mean differences from the allocations in the constant cell and resulted in significantly *lower* satisfaction and fairness than did that in the equality cell! In fact, the appeal–compensation cell did not differ from the average of all the constant cells and was significantly lower than the average of the rest of the improvement cells. The means for the satisfaction and perceived fairness measures are presented in Table 2.

Total Satisfaction and Fairness Measures

Subjects were asked to indicate their satisfaction and perceptions of fairness of the *total* allocations. The improvement main effect was significant: total satisfaction $F(2, 72) = 7.93$, $p < .001$, and total fairness, $F(2, 72) = 4.14$, $p < .05$. The pattern of means indicated that subjects were more satisfied with, and felt there was more fairness in, the total allocations when there was an improvement in the second half than when there was not. It should be noted again that subjects' total allocations were *identical* in every condition. Finally, the behavioral measure of number of items transcribed yielded no significant effects.

Discussion

The focus of the present research was to examine how disadvantaged parties in a relationship experience improvements of varying magnitudes as a function of the procedures by which these increases in their objective outcome level are introduced.

Evaluation of the Improvement

The main effect for the improvement factor indicates that subjects were more satisfied and felt that the allocator had been more fair when their pay improved in the second half than when it did not. This is consistent with a hedonistic view of human beings as motivated to maximize their outcomes. The demand for compensation is a popular response to inequity (Leventhal & Bergman, 1969), because the disadvantaged party benefits materially, as well as psychologically (with the reduction of "inequity distress"). The present results indicate that in general, compensation will be preferred to no compensation, even if the amount is not sufficient to restore overall equity.

This main effect was qualified by a Voice × Improvement interaction. To facilitate the presentation, the evaluation of the improvement will be discussed within each level of voice separately.

Mute conditions. In the mute conditions, subjects were more satisfied when their outcomes increased then when they did not. The two levels of improvement did not produce differential satisfaction, although the com-

pensation mean was higher than the equality mean. It is likely that the positive experience of the improvement resulted from the increased outcomes exceeding subjects' comparison levels (CL; Thibaut & Kelley, 1959). Since the increase occurred beyond subjects' control, their CL was probably not affected by the higher outcomes and remained rooted in the allocations of the first half. The result was a positive outcome–CL discrepancy in the improvement cells, which was absent in the constant cell where outcomes remained at CL.

Threat conditions. In the threat conditions, the pattern was similar to that described for the mute conditions. Subjects were more satisfied when they were successful in forcing the allocator to give them a larger share of the pay than when they were unsuccessful. This pattern of means is clearly counter to the predictions from the expression, attribution, and derogation hypotheses. It seems that voice per se is not sufficient to produce discontent with improving outcomes. Subjects in the threat conditions were able to voice their feelings during the procedure, the improvements represented a retreat by the allocator from his or her initial "tough stance," and the threat certainly could have been interpreted as "external pressure," yet subjects were *more* satisfied in the improvement cells than in the constant cell. Thus, it may require special types of voice to produce the discontent effect. This possibility will be discussed further below.

The question for now is, Why were subjects satisfied in the improvement conditions? Certainly their outcomes were higher than they had been in the first half. It may also have been that the successful exercise of power and the sense of efficacy it provided was itself satisfying (cf. Wortman & Brehm, 1975). The voice main effect, which showed highest overall satisfaction in the threat condition, is consistent with this combination of hedonic satisfaction and perceived control interpretation. An alternative explanation of the voice main effect relies on subjects' beliefs about the "bonus session," during which they thought they would actually have an opportunity to carry out their threat to deliver a burst of noise into the allocator's headphones. Perhaps the anticipated future contact caused them to be more attracted to the allocator (cf. Darley & Berscheid, 1967) and thus to evaluate his or her actions positively as well. Measures of liking for the allocator were included on the final questionnaire to tap these feelings in the second half, and overall as well. In both cases, the voice main effect was not significant (Fs < 1), making this explanation quite unlikely. A final point is that Thibaut and Kelley (1959) would predict that the improvement, having come about under subjects' control, would contribute to the CL, causing it to rise and eventually blunt the satisfaction associated with the increase. We will say more about this later.

Appeal conditions. The pattern in the appeal conditions deviated somewhat from the predictions, but what did happen seems to be of great theoretical interest. Recall that the predicted pattern required discontent to be highest in the compensation cell and least in the constant cell.

Subjects in the constant cell did not show signs of accepting their continued low outcomes, as one might expect if they had perceived the constant allocations as representing a denial of their right to more pay. Satisfaction in this cell was not higher than in the improvement conditions, as had been hypothesized, and in fact did not differ from the constant cells in the mute and threat conditions. Perhaps this difference between the present study and Folger's (1977) may be explained by differences in the clarity of the inequity induction. The opportunity to voice objections came after *five* periods of inequitable allocation in the present study as compared with only two in Folger's study. Our subjects' beliefs that they had been unfairly treated and were deserving of compensation may have been less subject to change following the allocator's response because of this increased experience. In this regard, the present study probably represents more adequately the state of disadvantaged groups in society, whose beliefs about their own entitlement are not easily shaken.

In the improvement cells, satisfaction was lower in the compensation than in the equal-

ity cell despite the fact that the improvement was objectively larger in the former. It had been expected that bringing subjects closer to the goal of overall equality without reaching it would constitute a greater violation of expectations and produce more dissatisfaction. Overall equity had been assumed as the criterion of fairness, since satisfaction was high in all of Folger's "equity" cells and since the messages sent by subjects in our voice conditions stated that the *total* shares should end up equal. However, the mean satisfaction in the equality cell (8.3 on the 11-point scale) is really too high to be called discontent. Some theoretical modifications appear necessary.

Subjects were clearly dissatisfied with the initial allocations (according to their responses to the first questionnaire, to be discussed below) and felt that they ought to be compensated (28 of 30 subjects in the appeal conditions actually chose the "appeal" message). However, they may have been somewhat uncertain about the level of compensation to expect until they experienced the improvements during the initial pay periods of the second half. We are now suggesting that the magnitude of the improvement given by the allocator served to legitimize one of several acceptable standards. In the equality cell, subjects experienced equal shares (12¢–12¢) in each of the initial periods of the second half. The allocator was thus communicating that a "proximal" standard of "fairness from now on" was the appropriate fairness criterion. In fact, the remaining allocations exactly matched this standard. In terms of relative deprivation, subjects received what they and the allocator had decided was fair, and they felt quite satisfied. In the compensation cells, the initial improvement gave the subjects more than the allocator (14¢–10¢ and 15¢–9¢ in Pay Periods 6 and 7, respectively). This division communicated to the subjects that they deserved not only equal treatment but also compensation for the initial unfairness—a "distal" standard. Later allocations failed to match these expectations, resulting in a strong sense of discontent. In the words of one subject in this condition who wrote in the margin of the final questionnaire, the allocator "attempted to co-opt me by giving me a little, but not enough to make fair allocation."

Further evidence on this point comes from the fact that the fairness measure was highly correlated with the satisfaction measure we have been discussing (within-cells correlation = +.59). Subjects not only felt less satisfied in the compensation than in the equality cell but also felt the allocations to have been less fair. This is exactly what one would expect if there existed a greater discrepancy between deserved and experienced outcomes in the compensation cell. In addition, a recently completed study by deCarufel (in press) directly manipulated the level of the standard and the magnitude of the improvement. The results indicated strong discontent when the distal standard was legitimized but "only" the proximal standard was matched by the improvement.

The Role of Initial Inequity

One final matter requiring comment is the role of the initial inequity. The precondition of initial deprivation was assessed with the first questionnaire, after Pay Period 5. Subjects were clearly dissatisfied ($M = 1.75$) and felt the allocations to have been unfair ($M = 1.67$). It is obvious however that in order to manipulate the second-half allocations systematically, this difference had to result in different total allocations or correspondingly greater initial inequity in the improvement cells. Because of our interest in the evaluation of identical totals differentially distributed over time, we decided to allow initial inequity vary with the improvement.

This is also, by the way, how Folger (1977) chose to deal with this dilemma. Fortunately, in the present study subjects' responses to the first questionnaire afford a method of assessing whether this inevitable confounding in any way damages the interpretations offered above. It might be suggested, for example, that if subjects were initially more dissatisfied in the compensation cell, then the results in the appeal conditions could simply reflect a continuation of these trends. Alternatively, it might have been the greater initial inequity

that caused subjects in the equality and compensation cells to use different standards to evaluate the improvement right from the start. The first point to note is that there was *no* difference in satisfaction after the first half across levels of the improvement factor ($p > .15$) despite the objective differential inequity. There was, however, a main effect for the improvement factor on the fairness measure, $F(2, 72) = 6.75$, $p < .01$. The pattern of means (constant = 2.5; equality = 1.0; compensation = 1.5) indicated that subjects were *less* dissatisfied in the constant cells than in either of the improvement cells ($p < .01$ in each case), which did not differ, $t(58) = .17$, *ns*. Thus, with the lack of a consistent satisfaction–fairness difference across the improvement factor and no difference between the improvement cells on *either* measure, any conjectures based on the effects of this differential inequity on evaluations of the subsequent improvement would appear less plausible. What these measures do show, however, is massive deprivation in *all* of the cells prior to the second half (recall that the means were under 2 on the 11-point scale).

Finally, it might be noted that the de-Carufel (in press) study mentioned above held initial inequity constant and allowed the final totals to reflect the improvement. Similar patterns of discontent with improvement were evident in that study as well, reinforcing the fact that experiencing discontent following outcome improvement does not require initial differences in degree of inequity.

Total Satisfaction and Fairness Measures

The main effect for the improvement factor was significant for both the total satisfaction and total fairness measures, despite the fact that the total outcomes in every condition were *identical*. This result clearly reflects the fact that the second-half allocations carried more weight in determining total satisfaction and fairness than did those of the first half. This recency effect may be due to the later allocations *replacing* the earlier ones (cf. Jones & Goethals, 1971) as indicators of the allocator's intentions. Evidence for this point comes from an auxiliary measure from the final questionnaire that asked subjects to indicate what they believed the allocator *now* felt they deserved. The main effect for improvement was significant, $F(2, 72) = 9.67$, $p < .001$, indicating that subjects in the improvement cells perceived that the allocator regarded them as more deserving than did subjects in the constant cell. These order effects point out the importance of taking into account how outcomes are distributed in time, as well as how the final totals come out, in considering the effects of outcome distributions on satisfaction and perceived fairness.

General Discussion and Conclusions

The major theoretical tool guiding the present experiment has been that of relative deprivation. The alternative mechanisms based on the operation of voice per se (expression, attribution, derogation) received no support from the pattern in the threat conditions. However, the analysis of the appeal conditions based on the "illegitimate violation of legitimate expectations" received support, both from the divergence of the threat and appeal patterns and from the convergence of the satisfaction and fairness measures within the appeal cells.

Most of the research conducted within the relative deprivation framework is concerned with "static" comparisons of one person's outcome total with another's total outcomes. The present article suggests two additional matters that contribute to an individual's satisfaction with his or her outcome level: "dynamic" comparisons of outcome distributions *over time* and procedural circumstances surrounding the distributive actions of the allocator (cf. Thibaut & Walker, 1975).

The effects of allocation schedule and procedure may contribute to satisfaction beyond the effects of the final totals, because these factors may precipitate changes in the standards by which outcomes are evaluated. It was mentioned earlier that perhaps satisfaction in the threat conditions would eventually be lower than in the mute conditions. The CL would rise, since the outcomes increased under the subject's control, and blunt the effect of the improvement. This is the classic analysis

of CL derived from Thibaut and Kelley (1959). Let us refer to this as a "market-type" CL, because it rises and falls with experienced outcomes.

There may be other standards, however, that are developed out of social interaction. In the appeal conditions, it was suggested that the nature of the voicing of opinions and the allocation schedule interacted to invoke various "normative" standards of fairness such as equality or full equity, against which the subsequent allocations were evaluated. Let us refer to this type of CL as a "contract-type" standard, because the fairness principle binds the participants to a particular standard. This would seem to be an instance of a more general process by which standards are negotiated by two (or more) parties and in which the outcomes of the interaction are evaluated in terms of each's obligations under that contract. This type of standard has not been explicitly recognized in the relative deprivation literature, which has focused almost exclusively on temporal (past outcomes) and social (others' outcomes) standards. Yet the interaction of type of standard and pattern of allocation is potentially important. For example, with a market-type CL, gradually improving outcomes that *exceed* CL would lead to the greatest satisfaction, whereas with a contract-type CL, sudden shifts, corresponding to renegotiations, followed by stable periods in which the allocations *match* the terms of the contract would produce greatest satisfaction. According to this logic, the threat conditions and the appeal conditions could still be distinguished when examined over a longer time period.

The present results provide another demonstration of the importance of the subjective evaluation of outcomes, rather than the objective level of outcomes, in determining satisfaction and feelings of fairness with dynamic, or changing, outcome distributions. This finding is particularly striking because outcome improvement would seem, on an intuitive basis, most likely to result in high satisfaction. There are some interesting implications for the evaluation of improvements by disadvantaged groups in society. One especially disturbing one is that those who use violent means to extract the increase would feel satisfied, and those who use nonviolent means would not. A future research direction might be to examine how subjects who have been in some of the conditions of this experiment would respond to a *choice* of voicing strategies, violent and nonviolent, before an additional series of pay periods. One might predict that the threat subjects who felt good about their recent outcomes would choose the threat message again. Those in the appeal-compensation cell, who objectively benefited from their nonviolent approach yet remained dissatisfied, might be prone to choose something other than the appeal again—perhaps the exercise of whatever form of power is available to them. These possibilities underscore the importance for administrators of ameliorative social programs to be very careful about triggering rising expectations in nonviolent groups and reinforcing the actions of violent ones.

To understand how people communicate information about others and make memory-based interpersonal judgments, it is necessary to understand how person impressions become organized in memory. Consistent with recent research in cognitive psychology on thematic organization of information in memory, Experiments 1 and 2 found that subjects were able to recall (as well as recognize up to a week later) descriptive traits that were relevant, as opposed to irrelevant, to an initial impression judgment. Furthermore, they tended to use judgment-relevant characteristics when asked to freely describe the stimulus person. Subjects' memory for the initial impression judgment itself was excellent and not measurably affected by the relevance of the stimulus information upon which it had been based. A third experiment investigated two possible ways in which thematic organization of an impression might influence a subsequent memory-based judgment about a person. Consistent with other recent research, it was found that when making memory-based decisions, subjects relied on memory for an earlier thematic judgment rather than on memory for descriptive stimulus cues.

A great deal of research in impression formation has been directed toward studying how people integrate items of person information for the purpose of making a single, stimulus-based judgment. "Stimulus based" is used to refer to the fact that such judgments are based on descriptive information provided by the experimenter simultaneously with, or immediately prior to, the time the judgment is made.

Two limitations to this research can be identified. Most day-to-day judgments that people make about each other are "memory based" rather than stimulus based. That is, they are based on a sampling of thoughts from a cognitive representation of the person that a perceiver has built up over time (years in most cases) and stored in memory. To understand the way in which people make memory-based judgments, it is necessary to understand how they organize person information in memory and draw on that information in later social behavior.

A second limitation of most previous work in impression formation is that attention has been focused almost exclusively on the process of making judgments. Yet, a great deal of interpersonal communication involves transmitting facts rather than making judgments. People share remembrances of others' actions, appearance, and other characteristics. Sometimes it is necessary to recall information

Portions of these experiments were reported at the annual meetings of the American Psychological Association, Chicago, September 1975, and the Midwestern Psychological Association, Chicago, May 1976. The research was supported by National Science Foundation Grant GS-38604.

about others, whereas at other times it is necessary to decide whether someone else's remembrances are accurate. (These two situations correspond to the recall and recognition tasks used in memory research.)

There are, therefore, two important social consequences of how person impressions are organized in memory. These are (a) how people remember previously acquired person information when it must be transmitted or judged for accuracy, and (b) how memory is drawn upon when a judgment is made. Both these questions are examined in the present article.

Thematic Organization of Impressions

Verbal learning research has demonstrated that memory for stimulus events can be organized around a superordinate theme. For example, it has been shown that sentences are more easily remembered when they are preceded by a thematic title than when no title is provided (Bransford & Johnson, 1973; Dooling & Mullet, 1973). Other research investigating how people remember written texts indicates that a salient theme helps determine what specific items, from a set of items, will later be recalled (Frederiksen, 1975; Rumelhart, 1975; Schank, 1975a, 1975b; Thorndyke, 1977). Finally, it has been found that a salient theme not only influences what factual information is remembered but also what inferences are likely to be made about a stimulus event (Picek, Sherman, & Shiffrin, 1975; Potts, 1972; Sulin & Dooling, 1974). Generally, the inferences people generate and remember tend to be relevant to, and congruent with, the theme that is salient when the stimulus information is initially considered.

Little is known about the themes that serve to organize people's impressions. Some work has shown that distinctive characteristics of a person may serve as an organizing theme. Asch (1946) originally suggested that certain central traits, such as warm and cold, serve as organizing frameworks for people's impressions. It has been shown that memory for information about a person can be organized around traits (Cantor & Mischel, 1977) or around a person's occupation (Anderson, 1977; Anderson & Hastie, 1974).

Rather than seek additional classes of person characteristics that are used as organizing themes, the present research examines whether the act of making an impression judgment will, in and of itself, influence the nature of memory organization. It is often the case that a person's first encounter with another is in a context that calls for a decision or judgment. For example, it may involve something as simple as deciding whether to continue a conversation or something as consequential as offering a job to the other. In both cases the person is receiving and organizing information about the other while actively engaged in making a judgment.

All three studies in this article required subjects to make an occupational suitability judgment (e.g., would this person be successful or unsuccessful as a dentist?) at the time they initially received information about a stimulus person. If such a judgment serves as an organizing theme for a person's impression, this judgment should affect memory (and subsequent memory-based social behavior) in the ways discussed above. Memory for the stimulus features of the person should be affected by the occupational theme. Occupation (theme)-relevant stimulus information should be better remembered than theme-irrelevant information. Furthermore, subsequent judgments and inferences about the stimulus person should be congruent with the thematic organization introduced by the judgment.

The first two studies reported here investigated the effects of a judgment on memory for information used to describe a person. Both recall (Experiment 1) and recognition (Experiment 2) memory were examined. Experiment 3 investigated two possible alternative ways in which thematic organization of an impression might influence a subsequent memory-based person judgment.

Experiment 1

If an initial judgment organizes a person's impression of another, this should be reflected both in the information that is later remem-

Table 1
Mean Number of Judgment-Relevant and Judgment-Irrelevant Traits Recalled: Experiment 1

Stimulus person replication	Trait relevance	
	Relevant	Irrelevant
1	2.69	2.25
2	2.44	2.06
3	2.56	1.81
4	2.25	2.25
M	2.49	2.09

Note. Cell $n = 16$. Scores in each cell could range from 0 to 4 traits.

bered about the person and in the attributes that are used to describe the person. In Experiment 1, subjects were asked to make occupational suitability judgments about stimulus persons described by traits that were both relevant and irrelevant for making the judgment. Afterwards, the subjects were asked to recall the descriptive traits and list additional traits they thought the person might possess. These inferred traits were evaluated for relevance to the occupational judgment. It was expected that subjects would (a) recall more judgment-relevant, as opposed to judgment-irrelevant, traits and (b) describe the person with more judgment-relevant (as opposed to irrelevant) characteristics.

Method

Subjects. Subjects were 116 male and female undergraduates from Ohio State University who participated in partial fulfillment of an introductory psychology course requirement. Of these, 12 assisted in selecting the stimulus materials, 64 participated in the experiment proper, and 40 were used to judge the relevance of the subject-generated descriptions. Where appropriate, subjects were randomly assigned to the experimental conditions.

Stimulus materials. Two pairs of occupations and four eight-trait person descriptions (two for each occupation pair) were used as stimulus materials. The occupations were academician and sportsman (Occupation Pair 1) and comedian and pilot (Occupation Pair 2). The person descriptions accompanying the first occupational pair contained four traits relevant to performance as an academician (e.g., logical, studious) and four traits relevant to performance as a sportsman (e.g., fearless, fast moving). The person descriptions accompanying the other occupational pair contained four traits related to performance as a comedian (e.g., humorous, theatrical) and four traits related to performance as a pilot (e.g., accurate, decisive). The traits for each person description were selected by having five subjects generate adjectives they considered to be relevant to one occupation within a pair but not to the other (e.g., relevant to academician but not to sportsman). These traits were subsequently rated by seven independent judges, and those traits were selected that received the highest ratings of relevance to one of the occupations within a pair but not to the other. Four traits relevant to academician in one of the Pair 1 person descriptions and four traits relevant to comedian in one of the Pair 2 descriptions were negative in evaluative tone. All the other traits were positive in tone.

Experimental procedures and design. Subjects were tested in small groups, and the stimulus materials were presented in booklet format. An introductory page explained that the research was concerned with how people predict success in an activity on the basis of personality trait information. Page 2 listed eight person traits and asked the subjects to consider the suitability of such a person for a designated occupation. Subjects were permitted to study the traits for 60 sec before turning the page. On three successive pages they were then asked (without looking back at the stimulus traits) to (a) record how well they thought the person would perform in the occupation mentioned on page 2 (a 21-point scale was used on which −10 was labeled "unsuccessful" and +10 was labeled "successful"), (b) recall as many traits as possible that had described the person, and (c) list additional traits that they thought would be characteristic of the person.

The experimental design was a $4 \times 2 \times 2$ mixed design with eight subjects per cell. The two between-subjects factors were (a) the four stimulus person replications and (b) which occupation (out of an occupation pair associated with a particular stimulus person) was judged by a group of subjects. The within-subjects factor was recall for the judgment-relevant versus judgment-irrelevant traits. This design insured that each subset of four traits was used equally often as a relevant and an irrelevant subset across the eight groups of subjects.

Results

Recall of stimulus traits. The mean number of relevant and irrelevant traits recalled for the four stimulus person replications is displayed in Table 1. In support of the experimental hypothesis, subjects recalled significantly more judgment-relevant traits than judgment-irrelevant traits, $F(1, 56) = 10.57$, $p < .002$. Although no difference appeared for Replication 4, no significant interaction between the trait relevance and stimulus per-

son replication factors was obtained ($F < 1.0$).

Subject-generated descriptions. The second experimental hypothesis was that the traits subjects use to describe the stimulus person would also be judgment relevant. To test this, it was necessary to determine for each subject the number of generated characteristics that were relevant to the judged occupation and the number that were irrelevant (i.e., more relevant to the other occupation in the pair). To do this, the traits that each subject generated were shown individually to two new groups of 10 subject judges. Each group of judges was asked to decide for each trait whether it indicated success or failure for one of the two occupations associated with the person description.

The criterion for determining the relevance of a generated trait to one of the two corresponding occupations was the absolute amount of consensus among the 10 judges as to whether it indicated success or failure for a particular occupation. For example, if 4 judges rated "outgoing" as indicating success as an academician and 6 judges rated it as indicating failure in this profession, while 7 out of 10 judges from the second group rated the trait as associated with success as a sportsman, the trait was scored as being more relevant to sportsman than to academician. This is because there was greater consensus among the judges as to the trait's implications for sportsman (7/10) as compared to academician (6/10). Traits for which the degree of consensus was a tie were not included in the data analyses.

The analysis of subjects' inferred characteristics paralleled the $4 \times 2 \times 2$ mixed design used for analyzing the recall data. The within-subjects factor in this case consisted of the two categories—judgment relevant versus judgment irrelevant—to which the inferred traits had been assigned.

The mean numbers of relevant and irrelevant inferred traits for the four stimulus person replications are displayed in Table 2. The means are generally consistent with the experimental hypothesis. The statistical analysis produced a main effect of borderline significance for occupation relevance, $F(1, 56) = 3.29$, $p < .08$, and no interaction between relevance and person description replications ($F < 1.0$).

Table 2
Mean Number of Judgment-Relevant and Judgment-Irrelevant Inferred Traits: Experiment 1

Stimulus person replication	Trait relevance	
	Relevant	Irrelevant
1	2.19	1.50
2	2.19	1.25
3	1.81	1.88
4	2.25	1.44
M	2.11	1.52

Note. Cell $n = 16$. Scores in each cell could range from zero to as many additional traits describing the person as the subject wished to list.

Because of the borderline significance of the relevance effect, an additional analysis was conducted on the percentage of judgment-relevant items out of each subject's total number of generated implicational associates. This analysis revealed a significant effect for relevance in the predicted direction, $F(1, 54) = 5.83$, $p < .02$.

Discussion

Subjects in Experiment 1 remembered judgment-relevant traits better than judgment-irrelevant traits and used more judgment-relevant characteristics to describe the stimulus persons. This finding is consistent with the notion that an initial judgment thematically organizes an impression. However, before such a conclusion can be drawn, additional evidence is needed. In the present experiment subjects were asked to remember the stimulus traits immediately following their judgment. Consequently, their recall may have represented short-term, as opposed to long-term, memory organization. Before concluding that a judgment organizes an impression, it would be necessary to demonstrate the persistence of the effect over an extended period.

A second type of evidence needed to establish the organizational properties of a judgment on an impression would be to demon-

strate the relevance effect in a memory recognition test as opposed to a recall test. This would have both practical and theoretical implications. Practically, during social interactions people engage in both types of memory tasks. Theoretically, the two kinds of memory tasks depend to varying degrees on different cognitive processes. Several theorists (Anderson & Bower, 1972; Kintsch, 1968) view recall as a two-step process in which information items are first searched for in memory and then compared with the item being sought. A recall test involves both the retrieval and comparison processes. In a recognition test, the items are supplied, making the comparison processes of primary importance. Testing the organizational properties of a judgment using a recognition task would have implications for whether the locus of the relevance effect lay in the retrieval or comparison processes.

It has been shown that an organizing theme is generally better remembered than the individual items of information upon which it is based (Bartlett, 1932; Frederiksen, 1975; Kintsch, Kozminsky, Streby, McKoon, & Keenan, 1975; Mandler & Johnson, 1977). Consequently, a further type of evidence that would help establish the organizational properties of a judgment would be evidence that the judgment (i.e., the organizing theme) is well remembered and unaffected by the relevance of the information upon which it is based or by the passage of time.

To further investigate how a judgment organizes an impression, Experiment 2 examined (a) whether the relevance effect would be present for recognition memory, (b) the persistence of the relevance effect over time, and (c) subjects' memory for an early judgment made about a person.

Experiment 2

Subjects in Experiment 2 were asked to make an occupational suitability judgment about a stimulus person and then to (a) recall the judgment they had made and (b) identify in a recognition test the traits that had been used to describe the person. The independent variables in the 2 × 2 × 2 between-subjects design were (a) whether the memory tests were administered 1 day or 1 week after the occupational judgment, (b) whether the stimulus traits were relevant or irrelevant to the occupational judgment, and (c) a stimulus person replication factor. Several hypotheses were proposed concerning the effects of these factors on subjects' memory for their judgment and the stimulus traits.

As in Experiment 1, it was predicted that subjects would be more accurate when the traits were relevant, as opposed to irrelevant, to an earlier occupational judgment they had made. This was expected to be true both 1 day and 1 week following the judgment.

Several investigators (Bartlett, 1932; Sulin & Dooling, 1974) have found evidence that subjects use a salient theme to help "reconstruct" related events or stimuli. Such reliance on the theme would likely increase with the passage of time as ancillary cues from the experimental setting become less available to assist subjects in remembering the stimulus traits. The assumption that subjects increasingly use the theme to help reconstruct the traits in a memory test led to several additional predictions. The first of these was that subjects' intrusion errors (i.e., traits identified as stimuli that were not part of the original person description) would be judgment relevant. It was further hypothesized that after a week, as compared to a day, (a) subjects would make more mistakes in recognizing the traits, and (b) the relevance effect for both recognition errors and intrusion errors would be greater.

This reasoning also implies that memory for the theme should be superior to memory for individual items of person information. Unfortunately, there is no way of directly comparing memory for an occupational judgment with memory for descriptive person traits. First, each may be of different familiarity to the subjects. Second, in the course of the experiment, subjects are exposed to several traits but to only one occupation. Nevertheless, the question of subjects' ability to remember their occupational judgment is interesting for two reasons. First, there has been little previous research that directly examines memory for an initial impression

judgment. Second, as explained, subjects' ability to remember a judgment is pertinent to the question of whether a judgment thematically organizes an impression. For these reasons, subjects were asked to recall their occupational judgment when they returned for the second experimental session. It was hypothesized that (a) the relevance of the stimulus information would not effect how well the judgment could be remembered and (b) memory for the judgment would be good and unaffected by whether the memory test was administered 1 day or 1 week later.

Method

Subjects. Subjects were 130 male and female undergraduates from Ohio State University who participated in partial fulfillment of an introductory psychology course requirement. Each subject was randomly assigned to one of the eight experimental conditions.

Stimulus materials. The stimulus materials used in Experiment 2 consisted of two occupations—pilot and comedian—and two groups of 22 traits. These traits were selected from the traits generated by subjects in Experiment 1 to describe the stimulus person evaluated as a comedian or a pilot. The 22 traits in one group consisted of traits that the judges agreed implied success as a comedian, but about which there was low agreement as to whether they implied success as a pilot (e.g., talkative and artistic). The second group of traits were selected to be relevant for judging success as a pilot but low in relevance for judging success as a comedian (e.g., accurate and punctual). From each group, 11 traits were randomly selected to serve as a stimulus person description, and the remaining 11 traits were used as foils in the trait recognition test.

Experimental procedure and design. The subjects were tested in small groups of two to four people, and the stimulus materials were presented in booklet format. An introductory page explained that the research concerned people's ability to predict success in a specific occupation on the basis of personality trait information. Page 2 asked subjects to consider the suitability of a stimulus person for one of the two occupations. This person was described by 11 traits and a small photograph of a neatly dressed male. The subjects were permitted to review the traits and picture for 60 sec before being told to turn the page. On the next page subjects were asked to record their judgment of the stimulus person's suitability for the occupation on a 21-point scale anchored by −10 (very unsuccessful) and +10 (very successful). After recording their rating, subjects were scheduled for a second session either the next day or 1 week later. It was implied that the tasks undertaken in the second session would be unrelated to those completed in the first.

During the second session the subjects received a booklet headed by a picture of the stimulus person. They were first asked to recall the occupation on which they had previously evaluated the person. Next, on an evaluation scale identical to the one used in the first session, they were asked to recall their exact evaluation. Finally, on a separate page, the subjects were instructed to identify the 11 traits that had described the person. These traits were embedded among 22 additional traits, 11 of which were the remaining traits relevant to the occupational judgment the subject had made and 11 of which were relevant to the occupation the subject had not seen. Subjects were told to identify exactly 11 traits from the list of 33.

To summarize the design, half of the subjects were scheduled to return for the second session the next day, and half were scheduled for 1 week later. Half of the subjects judged the stimulus person on an occupation for which the stimulus traits were relevant, whereas half judged an occupation for which the traits were irrelevant. Finally, half of the subjects judged a stimulus person described by 11 comedian-relevant traits, and half judged a person described by 11 pilot-relevant traits.

Results

Seven out of the 130 subjects did not return for the second session. Consequently, the reported analyses are based on data from 123 subjects. The stimulus person replication factor (i.e., whether the stimulus person possessed comedian- or pilot-relevant traits) did not interact with either the judgment relevance or time factor for any of the dependent measures and is, therefore, not discussed further.

Recognition accuracy for the stimulus traits. Consistent with the results of Experiment 1, subjects made more recognition errors when the traits were irrelevant, as opposed to relevant, to their occupational judgment (Ms = 2.87 vs. 2.11, respectively), $F(1, 115) = 9.68$, $p < .002$. Furthermore, subjects made more errors in identifying the traits after 1 week as opposed to 1 day ($Ms = 2.92$ vs. 2.00, respectively), $F(1, 115) = 13.8$, $p < .001$. However, the prediction that the effect of trait relevance would be greater after 1 week than 1 day was not supported, $F(1, 115) < 1.0$ for the interaction.

Nature of subjects' intrusion errors. The 22 incorrect foils in the recognition test seen by each subject consisted of 11 traits that were congruent with the traits that had been

used to describe the stimulus person (i.e., relevant to the same occupation) and 11 traits that were incongruent with the description (i.e., relevant to the other occupation). When subjects made a judgment that was relevant to the descriptive traits, there was no reason for them to have intrusion errors from the 11 traits that were incongruent with the description, since these traits were incongruent with the judgment they had made as well. However, in the irrelevant conditions the 11 traits that were incongruent with the description were congruent with the judged occupation. Thus, to the degree that the judgment thematically organized subjects' impressions, there should have been an increase in the proportion of intrusion errors from the 11 description-incongruent traits. Furthermore, this tendency was expected to increase over time if subjects increasingly came to depend on a judgment-based reconstructive process in recognizing the traits.

An examination of subjects' recognition protocols indicated that significantly fewer than 50% of the intrusion errors were from the description-incongruent trait lists (overall $M = 16.2\%$), $F(1, 105) = 172.5$, $p < .001$.[1] Even in the irrelevant condition, only 20.8% of the intrusion errors were from the set of traits that were incongruent with the person description. The predicted tendency for subjects to have an increased percentage of description-incongruent intrusion errors when the occupational judgment they made was irrelevant (as opposed to relevant) to the person-description traits was marginally significant (Ms = 20.8% vs. 11.0%, respectively), $F(1, 105) = 3.64$, $p < .06$. However, this tendency did not increase with time (the Fs for both the time main effect and its interaction with the relevance effect were less than one).

Recall of the occupational judgment. It was hypothesized that subjects' memory for the organizing theme (i.e., the occupational judgment) would be good and unaffected by the passage of time or the relevance of the traits on which it had been based. To test this, an index was constructed that reflected each subject's ability to recall both the judged occupation and the position she or he marked on the evaluative scale. This index was formed by giving a subject a score of 2 for remembering both the occupation and the exact scale position, 1 for remembering only the scale position or the occupation, and 0 for remembering neither.

In support of the hypothesis that neither trait relevance nor the passage of time would affect subjects' ability to recall their judgment, there was no significant difference in the recall index between subject groups who returned 1 week, as opposed to 1 day, later (Ms = 1.72 vs. 1.79, respectively), $F(1, 115) < 1.0$, nor a significant difference between the relevant and irrelevant trait groups (Ms = 1.79 vs. 1.67, respectively), $F(1, 115) = 1.97$, $p < .20$. The interaction between these factors was also nonsignificant, $F(1, 115) < 1.0$.[2]

It would be expected that memory for the judgment would be better than memory for the traits. Although, as has been noted, the two cannot be appropriately compared, it is worthwhile to comment on subjects' excellent ability to remember their judgment. Across all conditions, 96% of the subjects remembered the occupation they had judged, and 77% were able to reproduce their exact rating on the 21-point scale; 97% were able to reproduce their initial rating within one scale position.

Discussion

The results of Experiment 2 provide four types of evidence supportive of the notion that an initial judgment thematically organizes a person's impression of another. First, consistent with the results of Experiment 1,

---

[1] It was necessary to omit 10 subjects from this analysis, since they made no recognition errors.

[2] In addition to the combined index, subjects' memory for their evaluation and judged occupation was analyzed individually. Subjects' ability to remember their evaluation was unaffected by either the relevance manipulation or the time factor. In addition, there was no effect for relevance on subjects' memory for the occupation they had judged. The only significant finding was a difference in subjects' memory for the occupation after a week as compared to a day. Five subjects out of 123 were unable to remember the occupation they had judged, and all five were in the week-delay condition ($p < .04$).

subjects were better able to recognize a set of descriptive person traits when they were relevant, as opposed to irrelevant, to a judgment they had made. Second, this relevance effect persisted over time and was present both 1 day and 1 week after subjects had made their judgment. Third, there was a tendency for an initial judgment to increase the percentage of intrusion errors from a set of traits that had not been part of the person description, but which were relevant to the judgment. Fourth, subjects' memory for the judgment they had made was excellent and not substantially affected by either the passage of time or variations in the relevance of the stimulus traits.

This fourth conclusion must be viewed with caution. Subjects' memory for their judgment was so good that a ceiling effect may have occurred that masked the effect of time and trait relevance on memory for the judgment. Nevertheless, the fact that subjects' memory for their early decision was exceptionally accurate up to a week later is consistent with the idea that the decision thematically organized their impression and that it remains prominently available in memory as part of their impression of the stimulus person. A consequence of this prominence is examined in Experiment 3.

The predictions stemming from the assumption that over time subjects increasingly rely on their judgment to reconstruct the stimulus traits were not supported. While there was a tendency for subjects' judgments to influence intrusion error rates, the passage of time did not strengthen this effect. Furthermore, time did not increase the tendency for judgment-relevant traits to be recognized better than judgment-irrelevant traits.

There are at least two possible explanations why an interaction between the relevance and time factors did not emerge for either type of recognition error. First, subjects may not have relied on a judgment-based reconstructive process to identify the traits. If this were the case, it suggests that the relevance effect is primarily the result of differential encoding of the stimulus traits rather than reconstructive retrieval processes.

A second possible explanation for the failure to find an interaction between relevance and time is a lack of sensitivity of the experimental method. This could have occurred for several reasons. First, as noted, recognition tests are more sensitive to comparison processes than to retrieval processes. The hypothesized effect may have been visible if a recall, rather than recognition, measure had been employed. Second, the person descriptions tended to provide subjects with an alternative theme to help organize and recall the stimuli. For example, when subjects in the irrelevant condition made a judgment about a pilot, all 11 descriptive traits were relevant to the profession of comedian. Thus, it was easy for them to spontaneously conclude that the person would make a good comic and use this decision to organize their impression. Such an occurrence could account for the high rate of description-congruent intrusion errors even when subjects made an irrelevant occupational judgment. In support of this interpretation, four of the five subjects who erred in recalling the occupation remembered having judged an occupation that was congruent with the descriptive traits they had seen (e.g., TV entertainer, showman).

Experiments 1 and 2 used recall and recognition memory to provide evidence about the organizational properties of a judgment on a person impression. These findings have direct implications for people's ability to accurately convey person information to others. First impressions are indeed lasting, at least in their effects on the information people later have available for communication.

There is a second issue of equal concern: If a judgment organizes an impression, it should be reflected in subsequent memory-based judgments that rest on the impression. This was tested in Experiment 3.

Experiment 3

Experiment 3 investigated how organization of an impression by a judgment affects subsequent judgments. The rationale and alternative experimental hypotheses can best be understood in light of the experimental task. This task consisted of describing a stimulus person with all positive, all negative, or

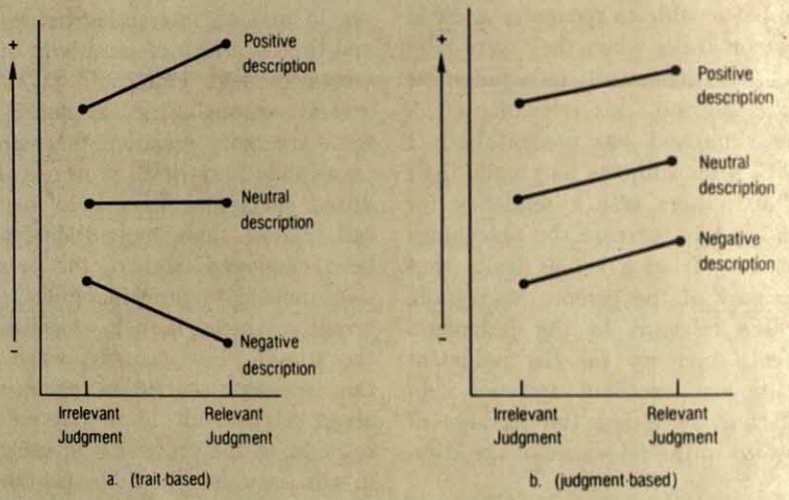

Figure 1. Possible patterns of attribute ratings as a function of judgment relevance and person description valence depending on whether the ratings are trait based (Panel a) or judgment based (Panel b).

all neutral traits and asking subjects to make memory-based ratings of the person's intelligence and friendliness. Before making these ratings, however (and while the traits were still available), subjects were asked to make an occupational judgment about the person. The occupational judgment was relevant to one of the attributes but not the other (e.g., research physicist to intelligence, but not to friendliness, and waiter to friendliness, but not to intelligence). It was expected that subjects' ratings of each stimulus person's intelligence and friendliness would be influenced by the relevance of the occupation they judged to each attribute.

The manner in which an occupational judgment might affect a memory-based attribute rating would depend on the way in which subjects draw on their memory for the person. For example, one way would be for them to recall traits that had been used to describe a person. Experiments 1 and 2 suggest that subjects would best remember traits relevant to their initial occupational judgment. If such memory bias exists, it should have the effect of polarizing subjects' attribute ratings when the occupation is relevant, as opposed to irrelevant, to the attribute being judged.

To understand this prediction, consider the specific case in which a subject is presented with a negatively described stimulus person. The subject is likely to conclude that the person would not be successful, regardless of whether the occupation being judged was research physicist or waiter. However, the occupation judged should affect later memory for the traits. In the case of research physicist, the subject would be likely to remember more intelligence-relevant traits, since intelligence is an important attribute for deciding if someone would be a good physicist, as compared to deciding if that person would be a good waiter. The more intelligence-relevant negative traits a subject can remember, the less intelligent the stimulus person is likely to seem (see Hamilton & Fallot, 1974 for a demonstration of this phenomenon in stimulus-based judgments). Just the opposite would be expected when a subject considers a stimulus person described by positive traits. The increased number of intelligence-relevant descriptive traits remembered following a relevant (as compared to an irrelevant) occupational judgment would be positive, thus making the person seem more intelligent. This interaction between person description valence and judgment relevance that would be expected if subjects based their attribute ratings on memory for the stimulus traits is graphically depicted in Figure 1(a).

It may be that subjects do not draw on memory for descriptive stimulus traits when

making memory-based judgments. Several studies have shown that people rely on their own cognitive responses to stimuli when making judgments (Greenwald, 1968; Lingle & Ostrom, 1979, in press; Petty, Ostrom, & Brock, in press). Lingle and Ostrom (1979), for example, had subjects make pairs of occupational judgments. They concluded that subjects based their second judgment on memory for their first judgment, since second-decision time was not affected by the number of traits that described a stimulus person, but was affected by the similarity of the first occupation to the second. Certainly, in the present Experiment 2, subjects' exceptional accuracy in remembering their occupational judgments suggests that such judgments are readily available in memory to be used as the basis for subsequent decisions.

If subjects were to base attribute ratings on memory for an organizational theme (i.e, the occupational judgment), rather than on memory for stimulus traits, the ratings should reflect the degree to which a particular attribute is stereotypical of the theme (occupation). For example, a subject would seem more likely to judge a person as intelligent if she or he had first judged the person to be a good physicist (as compared to a good waiter), since physicists are stereotypically more intelligent than waiters. One would also be likely to view a negatively described person as more intelligent following an intelligence-relevant occupational judgment, since a bad physicist is still likely to be stereotypically viewed as more intelligent than a bad waiter. Thus, if subjects were to base their attribute ratings on memory for the theme induced by an earlier occupational judgment, the expected pattern of results would be those depicted in Figure 1(b).

A $3 \times 2 \times 2$ within-subjects design was used to test if, and in what way, an initial occupational judgment would influence a subsequent attribute judgment. The three factors varied were (a) person description valence (positive, negative, neutral), (b) relevance of the occupation to the attribute (relevant or irrelevant), and (c) an attribute-rating replication factor (friendliness or intelligence).

Method

Subjects. Subjects were 82 male and female introductory psychology students who participated in partial fulfillment of a course requirement. Of these, 48 took part in the experiment proper, and 34 assisted in preparation of the stimulus materials. Subjects were randomly assigned to different stimulus material presentation orders used to counterbalance the experimental design.

Stimulus materials. Two classes of six occupations were used in the experiment. For one class, friendliness (but not intelligence) was the more relevant attribute for success (i.e., cab driver, airline steward, waiter, baggage porter, telephone solicitor, and shoe salesman); for the other class, intelligence (but not friendliness) was the more relevant attribute (i.e., geologist, research physicist, organic chemist, statistician, medical researcher, and aeronautical technician). These occupations were selected as follows: Two of the authors first chose 30 occupations that they believed to be of the intelligence-relevant class and 29 occupations they believed to be of the friendliness-relevant class from Hopke's (1975) list of occupations. Next, 18 introductory psychology students rated each of these occupations on 8-point scales according to how important they thought knowing about friendliness and intelligence would be for judging a person's aptitude for that occupation. The six intelligence-relevant occupations and the six friendliness-relevant occupations with the largest mean differences between friendliness and intelligence ratings were chosen for use in the experiment.

Three types of stimulus persons (positive, negative, and neutral) were constructed to be used in the experiment. This was done by first selecting 32 traits from three different ranges in Edwards's (Note 1) rescaling of Anderson's (1968) trait list: 250–349 (moderately negative), 350–449 (neutral), and 450–549 (moderately positive). The traits were randomly selected from within each range with the constraint that traits strongly implying anything about either friendliness (e.g., warm) or intelligence (e.g., stupid) were eliminated. Sixteen stimulus persons were then constructed by going through each set of 32 traits twice and randomly selecting (without replacement) eight groups of 4 traits each. To make the stimulus person descriptions of approximately equal relevance for judgments about both the intelligence and friendliness occupations, the 48 generated stimulus persons (3×16) were rated on 7-point friendliness and intelligence scales by a new group of 16 subjects. From each of the three groups of 16 scaled stimulus person descriptions, the 4 descriptions having the smallest absolute difference between their intelligence and friendliness mean ratings were selected to be used in the experiment.

Experimental procedure and design. Subjects were tested in groups of 10 to 20, and stimulus materials were presented in booklet format. The first two pages of the booklet explained that the experiment was

concerned with how people form person impressions from a limited number of descriptive traits and described the experimental task. This task consisted of having subjects make judgments of 12 different stimulus persons. Subjects first saw a list of four traits describing a person and were asked (on the same page) to rate the person on a 7-point scale according to how well they thought the person would perform in a particular occupation. After making this judgment, subjects were asked to turn the page and rate the person (without looking back at the stimulus traits) on 10 different attributes, again using 7-point rating scales. Two of the 10 traits were friendliness and intelligence. The eight attributes rated in addition to friendliness and intelligence were eight traits from Anderson's (1968) trait adjective list, which three of the investigators judged were unrelated to either friendliness or intelligence. These additional attributes were included to conceal the fact that the attributes of intelligence and friendliness were the only ratings of interest. The eight filler ratings were not analyzed.

Each subject judged all 12 stimulus persons, 1 on each of the 12 occupations. The 6 occupations in each class were paired with 2 stimulus persons described by negative traits, 2 described by neutral traits, and 2 described by positive traits. Twelve different rating-scale pages were constructed to be counterbalanced with the stimulus person and occupations. These pages differed only in terms of the order in which the attribute scales appeared. Each was constructed by first randomly assigning the friendliness and intelligence scales to two of the first five positions. The eight additional scales were then randomly assigned to the remaining positions on a page. Thus, for each of the 12 rating-scale pages that a subject saw during the experiment, the friendliness and intelligence ratings always occurred early in the list of ratings, but the order in which the rating scales appeared varied.

Counterbalancing of the 12 stimulus persons, 12 occupations, and 12 rating-scale pages was achieved by a Greco-Latin square. Twelve subjects were required in order for each possible stimulus combination to appear once. Four replications were undertaken by going through the Greco-Latin square four times, bringing the total sample size to 48. Two random orders were used for presenting the 12 stimulus sets.

When a subject initially judged a stimulus person on a friendliness occupation, the subsequent friendliness rating was considered relevant and the intelligence rating irrelevant. It was just the reverse when an intelligence occupation was used. Thus, this was a 3 (stimulus person type) × 2 (relevant or irrelevant occupational judgment) × 2 (friendliness or intelligence rating scale) design.

Results

Occupational suitability ratings. To test whether subjects' attribute ratings were trait based or judgment based, it was first necessary to show that the three levels of stimulus information led to distinctly positive, neutral, and negative occupational judgments on the 7-point rating scales. A repeated measures analysis of variance revealed a strong overall effect for type of stimulus person on subjects' occupation suitability ratings, $F(2, 29) = 223$, $p < .001$. The positive, neutral, and negative stimulus persons received ratings of 5.56, 4.08, and 1.88, respectively. There were no significant differences in the suitability ratings for the two occupation types, $F(1, 47) = 1.57$, nor for the Stimulus Person × Occupation interaction, $F(2, 94) = 1.23$.

Intelligence and friendliness ratings. If subjects' attribute ratings were based solely on memory for the initial stimulus information, occupational relevance should have polarized the ratings. If they were based on memory for the organizing theme, the relevance manipulation should have produced more positive trait ratings. It can be seen in Figure 2 that a strong relevance main effect was obtained, $F(1, 47) = 72.6$, $p < .001$. Even when the thematic judgment was negative (e.g., the person would make a poor research physicist), attribute ratings were more positive following a relevant, as opposed to an irrelevant, thematic judgment. The interaction between relevance and stimulus person valence, as predicted by the memory-for-traits hypothesis, was not significant, $F(2, 29) = 1.67$.

The data analyses did yield two interactions. The first of these was a three-way interaction between relevance, description valence, and attribute rating, $F(2, 94) = 3.50$, $p < .04$. Figure 2 shows that the two trait replications differed primarily in how relevance affected ratings of the negative stimulus person. The second interaction was a two-way interaction between relevance and the attribute ratings, $F(1, 47) = 10.6$, $p < .002$, resulting from the relevance effect being stronger for the intelligence attribute than for the friendliness attribute.

General Discussion

Psychologists have long been interested in the ways impressions are organized. Perhaps

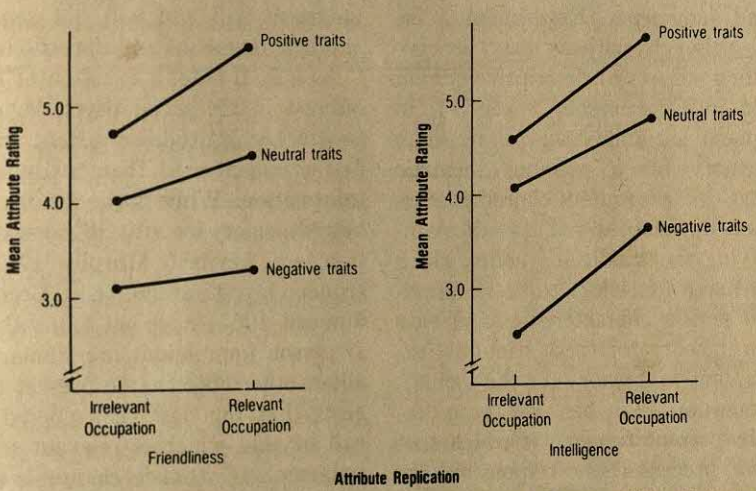

Figure 2. Mean friendliness and intelligence ratings as a function of occupation relevance and person description valence: Experiment 3.

this is because so much social interaction involves transmitting, receiving, evaluating, and acting on information about others. It has generally been assumed that each of these actions depends not only on specific facts that someone knows about another, but on how such facts are organized into a unified impressions. In spite of such interest, there has been little unanimity as to how impression organization should be conceptualized and studied. Asch (1946), for example, conceptualized an impression as a unified gestalt organized by central traits that provide meaning to, and relationships among, peripheral characteristics. More recent theorists (e.g., Cantor & Mischel, 1977; Markus, 1977) have viewed impression organization as the formation of prototypes or cognitive schemata that develop out of stimulus cues or experiences when these cues converge on a common concept.

The approach exposited in the present article conceptualizes impressions as being organized around a central theme that orders the availability in memory of impression-related cognitions. While stimulus configurations may be capable of imparting such organization (as when they are highly interassociated), the present studies investigated the organizational consequences of a judgment made when information about a person is initially received. The importance of investigating the thematic organizational properties of a judgment, as opposed to some other organizing factor, arises from the fact that people often receive information about others in a judgment context. From national elections to job interviews to psychology experiments, people perceive, organize, and encode information about others within a judgment context.

In support of the hypothesis that an early judgment thematically organizes an impression, Experiments 1 and 2 found that (a) the judgment itself was extremely well remembered up to a week after it had been made, (b) judgment-relevant information was better remembered than judgment-irrelevant information (again, up to a week later), and (c) the characteristics subjects used to freely describe the person tended to be judgment relevant. Each of these properties is consistent with the properties that research in cognitive psychology has established as characteristic of an organizing theme in prose or discourse.

While Experiments 1 and 2 investigated the general availability of person information within the context of a recognition or recall test, Experiment 3 examined what subjects access from memory in a judgment situation. Although integration theorists (e.g., Anderson, 1974) have developed algebraic models capable of describing how people combine information cues in a stimulus-based decision, there has been little research investigating what thoughts people access when they make

memory-based judgments. Experiment 3 indicated that although subjects may be capable of recalling subsets of descriptive stimuli (as indicated in Experiments 1 and 2), in certain judgment situations they draw more on their memory for a previous thematic judgment and its associated characteristics. One important, but unanswered, question concerns identifying the conditions under which subjects will make the effort to recall previously learned person characteristics and base a decision on memory for these stimulus features (rather than on memory for the theme).

Another question that has not been answered by the present research is which specific cognitive processes are responsible for the organizing properties of an early judgment on an impression. The fact that the relevance effect was obtained for recognition as well as recall memory suggests that encoding processes may have been partially responsible. This is also indicated by the finding that the relevance effect did not increase with time. If encoding processes do play a role, several mechanisms may be involved. For example, it may be that while considering the person descriptions, subjects generate and store in memory characteristics that are jointly associated with both the descriptive traits and the judgment they have to make. Several studies have demonstrated that people's internally generated thoughts are stored in memory and well remembered (Dosher & Russo, 1976; Greenwald, 1968). These inferred characteristics may later be recalled and serve both as a basis for subjects' descriptions and as a cue for remembering the stimulus traits.

An alternative explanation of the relevance effect could be that the judgment-relevant stimulus traits are processed more deeply (Craik & Lockhart, 1972; Craik & Tulving, 1975) and therefore are remembered better than judgment-irrelevant traits. Memory for these traits might then have served as the basis for subjects' judgment-relevant free descriptions. These, as well as other possible mechanisms, need to be explored by further research in order to establish the conditions under which an early (and perhaps a later) judgment will and will not serve as an organizing theme for an impression.

As a final note, a question of long-standing interest in the social psychological literature is whether attitude-consistent information is better remembered than attitude-inconsistent information. While some studies have found better memory for attitude-consistent information (e.g., Levine & Murphy, 1943), most subsequent investigations (e.g., Greenwald & Sakumura, 1967) have not found this to be true. If person impressions are similar to attitudes about other objects, the present research suggests that the best remembered information will be that which is relevant to an attitude judgment. If attitude change is equated with the reaching of a new attitude judgment, information should be best remembered when it is relevant to attitude change, not associated with attitude constancy.

Effects of Preparatory Information About Sensations, Threat of Pain, and Attention on Cold Pressor Distress

Howard Leventhal, Donald Brown, Saya Shacham, and Gretchen Engquist
University of Wisconsin—Madison

Pain experience is conceptualized as a combination of stimulus sensations (e.g., aching) and emotional distress. In Experiment 1, less distress was reported to cold pressor stimulation by subjects first told about stimulus sensations than by subjects who were uninformed or were told about symptoms of bodily arousal (e.g., tension). Adding a pain warning to sensation information blocked distress reduction, presumably by eliciting an emotional interpretation of the stimulus. In Experiment 2, subjects attending only to hand sensations reported less distress than subjects attending to their bodies. This decrease in the power of the stimulus to provoke emotion is presumably mediated by a schema of hand sensations formed by attention. In Experiment 3, subjects attending to hand sensations early in the immersion and distracting themselves later reported the same low levels of distress as did subjects who attended to hand sensations throughout. Subjects distracted throughout and subjects attending to hand sensations later showed no distress reduction. Therefore, stimulus schematization must precede distress reduction. Implications for distress control are discussed.

A number of controlled laboratory (Johnson, 1973; Staub & Kellet, 1972) and field (Cohen & Lazarus, 1973; Egbert, Battit, Welch, & Bartlett, 1964; Johnson, Kirchoff, & Endress, 1975; Johnson & Leventhal, 1974; Johnson, Morrissey, & Leventhal, 1973; Sime, 1976; Wolfer & Davis, 1970) experiments have demonstrated the value of preparatory information for the reduction of distress during exposure to noxious stimulation. Despite these positive findings, our picture as to how preparation reduces distress is not especially clear. We do not know which components of the preparation package affect particular indicators of distress, and we lack a detailed view of the process underlying distress reduction. Given these limits, it is not surprising that a variety of specific, often apparently competing, hypotheses are offered to account for the distress-reducing effects of preparation. For example, preparation is said to reduce distress if it stimulates moderate fear levels and preparatory behaviors (Janis, 1958, 1967); if it provides specific, accurate expectations about stimulus properties (Epstein, 1973; Janis, 1958; Johnson, 1973, 1975; Johnson & Leventhal, 1974); if it provides a neutral label to account for diffuse body reactions that would otherwise be labeled as fear (Nisbett & Schachter, 1966; Ross, Rodin, & Zimbardo, 1969); and/or if it enhances the individual's sense of control over the stressor (Geer, Davison, & Gatchel, 1970; Glass & Singer, 1972; Weiss, 1971).

None of the specific hypotheses appears adequate to account for the empirical find-

This research was supported by Grant SOC 75-02482 from the National Science Foundation to the first author. Experiment 1 was completed in partial fulfillment of the requirements for the Doctor of Philosophy degree awarded to Donald Brown by the University of Wisconsin—Madison. Experiments 2 and 3 were completed in partial fulfillment of the requirements for the Master of Science degree awarded to Saya Shacham by the University of Wisconsin—Madison.

ings. Thus, moderate levels of fear prior to stressor exposure are reported to innoculate against distress during exposure in some studies (Janis, 1958) but not in others (Cohen & Lazarus, 1973; Johnson, Leventhal, & Dabbs, 1971; Sime, 1976; Johnson, Rice, Fuller & Endress, Note 1). Perceived control is found to reduce distress from noxious stimulation in some studies (Geer et al., 1970; Staub, Tursky, & Schwartz, 1971, Experiment 2) but not in others (Brady, Porter, Conrad, & Mason, 1958; Pervin, 1963; Staub et al., 1971, Experiment 1). When control reduces distress, it does not always do so during actual exposure to the stressor (Glass & Singer, 1972). While no single study can possibly untangle the complete set of factors underlying these apparent inconsistencies, the three experiments reported here are designed to clarify at least one aspect of the problem, the role of stimulus interpretation or stimulus coding (e.g., Holmes & Houston, 1974; Lazarus, 1966; Leventhal, 1970; Sokolov, 1963) in distress reduction. This focus should not be seen as a rejection of the importance of prior fear level or of coping as important contributors to distress reduction; all of these factors are important elements in a complete picture of distress reduction. It is our assumption, however, that they can be better understood if we clarify the way the coding or interpretation of the stressor influences distress during impact.

The general thesis underlying the present experiments is that distress during stressor impact consists of both informational (sensory, stimulus attributes) and emotional (subjective distress or fear) components, which are usually integrated into a common experience (Beecher, 1959; Leventhal, 1970, in press; Leventhal, & Everhart, in press). Three questions are raised respecting the effect of coding or interpretation on the distress experience: (a) Can interpretation actually alter the total experience of stressor impact? (b) What aspects of the experience are actually altered (e.g., the sensory information or the emotional distress)? (c) How does the alteration take place? The three experiments reported here show that distress on impact can indeed be reduced by preparation. Second, they suggest that emotional distress (or suffering) is the component of the experience most likely to be altered by preparation. Third, they suggest that this change happens because identifying or focusing on the sensory properties of the stimulus in a nonthreatening setting leads to the formation of a template or schema of the stimulus that causes it to lose the power to provoke emotional reactions (Sokolov, 1963).

All three investigations study distress induced by cold pressor stimulation. The cold pressor test seems ideally suited for the study of coding or interpretation of noxious stimulation because it provides a rich array of sensory features (Mountcastle, 1968; Wolf & Hardy, 1943); has a relatively slow onset of distress induction, providing time for the impact of mental operations (Wolf & Hardy, 1943); can be affected by psychological manipulations such as set (Barber & Hahn, 1962) and hypnotic analgesia (Hilgard, 1969, 1971); and is not so threatening an experience as to prevent manipulating threat level while holding physical stimulation constant (e.g., Teichner, 1965).

Experiment 1

Experiment 1 compared the level of distress reported during a cold pressor test of groups of subjects given three different types of preparatory information: (a) information on the distinctive features or *sensory* properties of the noxious stimulus; (b) information on the individual's likely overt and covert emotional or *arousal* reactions to the stimulus; and (c) information on the potential strength, *painfulness,* or *magnitude* of the noxious stimulus. Both sensation information and arousal information have been used to reduce distress and fear behaviors on impact with noxious stimulation, and both are presumed to do so because they affect expectations or interpretations of the stimulus. Magnitude or threat information, on the other hand, is expected to limit the operation of both sensation and arousal information. Experiment 1 compared six conditions, sensation information, arousal information, and control, each presented with or without high-

magnitude pain warnings. The specific reasoning and hypotheses for each of the conditions are presented in the following sections.

Sensation Information

Sensation information prepares the individual with a detailed preview of the tactile, thermal, and visual changes that he or she will experience during stressor impact. Johnson (1973) gave subjects sensation information about ischemic pain ("to feel pressure and sensations such as tingling and aching, followed by numbness, . . . arm and hand will be . . . pale and blotched") and in two experiments found substantially lower levels of reported distress for these subjects in comparison to control subjects given information on experimental procedures. There were no treatment differences, however, for reported strength of stimulus sensations; preparation affected only the emotional component of experience.

Beneficial effects of sensation information were also suggested, though less clearly so, in a study by Neufeld and Davidson (1971) and in a study by Staub and Kellet (1972), although in the latter study the investigators did not expect to find the reduction in distress reported for electric shocks by sensation-informed subjects, and it occurred only when the sensation-informed subjects were reassured that the shock was harmless. Finally, reductions have been observed in behavioral signs of distress (e.g., gagging and heart rates) for patients given sensation information the night before an endoscopic examination—a diagnostic test of the upper gastrointestinal tract in which the patient must stay awake and vary his or her position after swallowing and admitting a fiber optic tube (Johnson & Leventhal, 1974; Johnson et al., 1973). Similar effects in emotional distress reduction have been found during cast removal with children (Johnson et al., 1975).

Two hypotheses have been offered to account for the reduction of distress by sensation information. The first argues that the information provides the subject with accurate expectations against which to check stressor impact (Johnson, 1973, 1975). When expectations are accurate, uncertainty, surprise, and startle are minimized, and the individual will believe that the situation is under control. The second hypothesis takes the more inclusive view that sensation information alters the way the noxious stimulus is processed (i.e., it changes the schemata or codes that are integrated with the noxious input). If the subject processes the noxious input in terms of its informational properties and forms a schema of its sensory features, the input will lose the power to stimulate attentional and emotional responses, and there will be a gradual decline or habituation of the emotional (distress) component of the experience. This analysis suggests that the accuracy of the sensation information per se is not the critical factor in producing distress reduction. The critical factor is the schematization or coding of the input as a set of objective features, such as coldness, numbness, and pins and needles, rather than the schematization of the input as pain, fear, and uncertainty as to whether the skin will break and bleed, the flesh will be damaged, and so on (Engel, 1959; Leventhal, 1970, 1975, in press; Leventhal & Everhart, in press).

If the accuracy hypothesis is a sufficient explanation for the beneficial effects of sensation information, one might expect that any accurate information, whether it describes the sensory properties of the noxious stimulus or its painful magnitude, will reduce surprise and distress. Thus, warnings about the painfulness of the stimulus should be distress reducing, as is information about its sensory features. The processing interpretation, however, suggests that warning information is precisely the kind of preparatory input that might encourage encoding a stimulus as a threatening event (i.e., integrating the stimulus with emotional and pain memories that stimulate expectations and uncertainty about possibly harmful outcomes). This type of processing can occur regardless of the accuracy of the warning. The processing analysis is supported by Epstein's (1973) penetrating review of studies of the effects of prior warnings on subjects' reactions to the impact of noxious events. He points out that distress and emotionality are not reduced by high-

magnitude information (warnings that a stimulus will be painful), even if this information is accurate. Epstein found that subjects who expected the 10th of a series of tones to be very severe were more anxious than subjects who expected the tone to be of moderate or mild volume, and he found no evidence that the accurate information about stimulus magnitude reduced distress on impact (as measured by heart rate and skin conductance; Epstein & Clarke, 1970). To the contrary, the evidence suggested that magnitude information that established "an accurate expectation can amplify reactivity to a sufficiently threatening stimulus, at least initially" (Epstein, 1973, p. 103). The Staub and Kellet (1972) findings are consistent with this interpretation.

The accuracy and processing notions lead to quite different expectations, therefore, respecting the effects of preparation on distress to cold pressor pain. The accuracy hypothesis suggests that accurate information on sensations and magnitude of a stressor should reduce distress on impact because both types of information limit uncertainty and define anticipated harm. The processing hypothesis suggests that magnitude and sensation information will have different effects; sensation information will permit the schematization of the noxious stimulus and distress reduction, whereas magnitude information will establish a set for integrating the stimulus with emotional memory schemata that will enhance distress reactions. Thus magnitude information will cancel the effect of sensation information.

If we apply the reasoning described above to cold pressor stimulation, in which stimulus sensations and distress gradually become more intense, we can anticipate the following: If the accuracy hypothesis is true, (a) the group receiving sensation information and the high-magnitude pain warning will show the lowest levels of distress, the unprepared control group will show the highest levels of distress, and the sensation-only and pain-warning-only conditions will fall in between; and (b) the effect on emotional distress should appear early, or as soon as stimulation confirms the preparation. On the other hand, if distress reduction involves the more complex process of coding or schematizing the objective features of the stimulus—a process that can be disrupted by a pain warning—one would expect (a) lower distress ratings with sensation information and no pain warning, with the remaining conditions more or less the same, and (b) condition differences toward the latter part of the exposure period (i.e., after schematization takes place).

Arousal Information

Arousal information involves descriptions of emotional behaviors—the objective and subjective signs of arousal such as heart beating, hand sweating, tenseness, and so forth—which allow individuals to anticipate their overt and covert reactions to a noxious stimulus. Stimulated by Schachter's (Schachter, 1964; Schachter & Singer, 1962) revival of cognition–arousal theories of emotion, investigators have developed a variety of experimental paradigms in which they give subjects arousal information prior to exposure to a noxious stimulus. This information is usually presented along with misattribution information (i.e., information incorrectly linking the arousal signs to a neutral source). For example, Nisbett and Schachter (1966) gave subjects a placebo pill before exposing them to a series of increasingly painful electric shocks. The subjects were told that the pill would cause changes (misattribution) in their emotional reactions (arousal information), for example, heart rate, hand sweating, trembling, and so forth. Because the subjects were led to assume that their arousal behaviors were caused by the neutral pill rather than by the painful shock, they were expected to, and did, tolerate higher levels of shock.

Although the misattribution studies are interpreted as demonstrating that the neutral cognitive label redefines the subjects' emotional state they feel less frightened when they associate their arousal with a neutral pill than with a threatening shock, it is unclear whether the effect of the manipulation is due to the misattribution to the neutral source or to informing the subjects about their arousal behaviors (Leventhal, 1970, p.

172; 1974). Indeed, the major difference between misattribution and control subjects is the receipt of information on arousal behaviors by the former and the receipt of information on a series of irrelevant signs (suggestions that they will feel numbness, itching, etc.) by the latter. Consistent with this, Calvert-Boyanowsky and Leventhal (1975) found that arousal information per se was important in reducing subjects' fear-motivated avoidance behavior (i.e., arousal-informed subjects worked longer at puzzles to win money than at puzzles to avoid shock, whether their arousal was attributed to a "neutral" noise or to a threatening shock). They concluded, therefore, that arousal information and not the source of attribution (neutral noise vs. threatening shock) is the factor responsible for reduction in fear-motivated avoidance behavior.

The effects of arousal information are similar in some respects to those for sensation information, since arousal information appears to reduce avoidance behavior and is less effective in doing so when accompanied by warnings of high magnitudes of danger (e.g., Nisbett & Schachter, 1966). But there is little evidence to suggest that arousal information actually reduces distress on stressor impact. For example, while Calvert-Boyanowsky and Leventhal (1975) found that arousal information reduced the subjects' avoidance behavior, it did not change their subjective emotional state. Nisbett and Schachter (1966) also seem to have found much more substantial differences for avoidance behavior (shock tolerance) than for reports of distress, holding levels of shock constant. These findings raise the question, therefore, as to whether arousal information will actually reduce distress during cold pressor impact, and will do so only in the absence of high-magnitude pain warnings, or whether the experience of distress during cold pressor stimulation will be as severe for subjects with arousal information as for subjects without it.

It was our expectation that arousal information would not reduce distress on cold pressor impact, since it does not assist the subjects in forming a schema of the stimulus features, nor does it assist them in blocking out awareness of stimulus sensations. What seemed likely was that arousal information would prevent the subjects from becoming frightened by their own fear reactions, reducing, therefore, signs of distress-motivated avoidance.

Method

Design and Subjects

The experimental design crossed magnitude information (pain message vs. no pain message) with three information conditions: (a) sensory information, (b) arousal information, and (c) a control group given information on the procedure. Judgments or trials were a within-subjects factor. The magnitude information was included in a single sentence that informed the subjects that they would experience strong pain while their hands were in ice water. The reference to pain was omitted in the low-magnitude conditions. The sensory information message described the physical sensations the subjects would feel during and after the immersion of their hands in the water. The arousal information described specific arousal reactions that would occur during this same time period, and the control message described general details of the experimental procedure.

A total of 50 males were included in the analysis of the study (see Figure 1). While we know of no important sex differences in response to cold pressor or to the experimental treatments, the quit rate is slightly higher for female subjects, and to maximize experimental time we decided to use male subjects only in all three studies. These subjects were recruited from the introductory psychology pool and had completed and met the criteria for participation set by a questionnaire. The questionnaire was used to disqualify subjects who reported medical problems such as hypertension or other circulatory problems, rheumatic fever, heart disease or heart abnormalities, and asthmatic attacks or being on medication for asthma. Reports of any form of convulsion, prior frostbite, taking psychoactive drugs within the past 12 hours, or special medical problems requiring a physician's care (e.g., stomach ulcers) were also grounds for disqualification. One subject was disqualified because of a broken arm.

Experimental Setting

The subject was seated in a comfortable chair in a room containing little visible equipment. There was a low platform that held the ice water tank, three large metal filing cabinets, and a one-way mirror that was almost completely covered by a series of 8¼ × 11-inch color prints. A portable cart held the materials for attaching heart rate electrodes and the questionnaires for the initial portion of the experiment.

All equipment (a Grass polygraph used to record heart rate and skin temperature, a Panasonic videotape recorder used to record subjects' facial expressions, and a Sony tape recorder used to present instructions) was in an adjacent room. The two rooms were connected by an intercom, and the experimenter could view the subject through the spaces between the prints that covered the one-way mirror.

Procedure

Subjects were randomly assigned to the six experimental conditions, with the restriction that a complete replication of the design (a subject in each of the six cells) was run before beginning a second set of six. There were four experimenters, each aided by an assistant experimenter. The assistant placed the appropriate instruction folder on the subject's table, randomized and assigned the subjects to conditions, and gave the experimenter a code letter that indicated which instruction tape to play to the subject. The further precaution was taken of assigning new code letters to the experimental tapes halfway through the study.

The subject was conducted to the experimental room, where he donned earphones and listened to a brief introduction that stated that the study was one of a series of investigations on "psychological and physiological reactions to cold temperature" and advised the student that he could "quit the experiment now or at any time . . . without forfeiting (his) experimental credit."

Informational Conditions

The instructions for each condition were as follows:

(*Sensory information*). The cold temperature treatment that we mentioned will involve submerging your hand (to the wrist) in an ice bath. When you put your hand in the water, the first sensation will be one of extreme coldness. The feeling of coldness will last for a short period of time (around 20 or 30 seconds), and then you will begin to feel a number of different sensations. *The first of these is a sensation of pain, which will begin to get very strong around this time.* (This last sentence was eliminated in the low-magnitude message.) Along with this, you will begin to get a feeling of strong pressure on your hand. You may notice that the feeling of discomfort is not spread evenly around your hand but rather is concentrated in certain areas. For instance, you may begin to feel a tingling sensation in your fingers which seems to bite or burn. Your whole hand may throb after some additional time, and the joints of your fingers will begin to feel somewhat stiff.

After a while, the strong sensations will begin to fade. At this time you will feel a pinpricking sensation or a feeling that your skin is being pulled tightly across the back of your hand. This sensation will fade in your fingers and lower hand until you can feel only numbness. The prickly feeling will remain only in a ring at the point where your hand enters the water.

After your hand is removed from the water solution, you will be aware of a new set of sensations. First, there is a prickly feeling which is similar to a limb waking up. It starts in your fingers and moves slowly up the sides of your palm. You will also detect nervous twitching in the muscular pads of your palm and in your fingers.

(*Arousal information*). The cold temperature treatment that we mentioned will involve submerging your hand (to the wrist) in an ice bath. This experience produces many feelings and reactions in addition to the sensations you will feel in your hand.

When you first put your hand in the water, you will feel a sense of apprehension or anticipation. Almost immediately your whole body will begin to react to the temperature change. *One of the first feelings you will notice is the sensation of pain, which will begin to get very strong about this time.* (This sentence was omitted in the low-magnitude message.) You'll also be aware of additional feelings and reactions. Some of these will be similar to those feelings you have when you are experiencing an emotion such as fear or excitement. You may even be experiencing some of these reactions right now, such as butterflies in the stomach. You may notice that your other hand has begun to sweat. Along with this, you will feel yourself becoming more alert or awake. Generally, you will feel your whole body is exerting a great deal of effort. Your facial muscles, in particular, will show an increase in tension. You might feel your forehead raise and wrinkle. Tension will sometimes spread to other parts of your body—your arms, shoulders, and chest. After a few minutes, this muscle tension may cause a feeling of weakness in various joints and muscles in the legs and chest. After a while your emotional reactions and your feelings of tension will begin to fade.

Once you have removed your hand from the water, you will probably feel a lot of pressure being removed from your body muscles—this is relief. This relief may be accompanied by a surge of warmth and by the feeling of tension rapidly leaving your chest and arms.

(*Procedural information control*). The cold temperature treatment that we mentioned will involve an ice bath. This bath consists of a small bucket of ice-cold water. A cylindrical wire screen is used to keep the ice out of the center area of the bucket. Considering your normal body temperature of 98°, ice temperature represents a large environmental change. *For this reason, after your hand has been*

in the water a short period of time, the sensation of pain will begin to get very strong. (The last sentence was omitted in the low-magnitude message.)

The experimenter is presently preparing to take the physiological measures we need. He has already attached some measuring electrodes. These electrodes are part of a recording apparatus and are connected to a penlike oscillograph located in the next room. Before the next part of the procedure, the experimenter will take another physiological measure—blood pressure. The entire time your hand is in the water, the experimenter will be next door operating all of the recording apparatus, since it is necessary for him to adjust the equipment occasionally as your physiological reactions reach a peak and begin to fade, and he must make small notations on the settings which are being used for recording this rise and fall in your physiological reactions.

After you remove your hand from the water, the electrodes will remain attached for a short period of time. Finally, the experimenter will have some questions to ask you.

Each message terminated with the following instructions: "Your hand will be in the water for a 6-minute period unless you decide to remove it before that time. Now let's go over that again so that you will remember it clearly." All subjects were given a written copy of the appropriate message for their group.

Instructions on safety. At the close of the instructions specific to his condition, the subject was given the following information, which stressed that the experiment was harmless:

Some people who have participated in this experiment have expressed concern about injury to their hand. We want to assure you that under these conditions even ice-cold water cannot and will not cause any damage during the period of time you will be exposed to it. However, as a safety factor, we are monitoring skin temperature and will make certain that your hand does not reach freezing temperatures. There is absolutely no danger of any damage to your hand.

Measures

Mood ratings. Subjects were next instructed to fill out a Mood Adjective Checklist (MACL), because "your emotional feelings or moods at the moment may be related to some of the measures of physiological activity which we are taking. For this reason we would like you to fill out the mood and feelings rating scale located under the manila folder. We'd also like you to fill out the attached questions on your expectations at this point." When the MACL was completed, the experimenter again entered the room to take the subject's blood pressure. Two TV cameras and some additional TV equipment were on one of the cabinet shelves. One of the cameras was live and transmitting to the next room, so that the experimenter could observe the subject's behavior and score expressive reactions. None of the expressive ratings are reported, since very little expressive behavior was observed.

Sensation and distress ratings. After the experimenter took the subject's blood pressure, the ice bath and table were moved to the subject's right, and the experimenter displayed a sensation and a distress scale, which the subject was to use to make ratings during *and* following the immersion of his hand in the cold water. When the experimenter departed, the subject heard the taped instructions for rating sensation and distress during and after immersion of his hand in the cold water. He was told that sensation was "the physical intensity of what you will be feeling," and distress was "the amount of upset or distress the sensations cause." Each scale was printed in the vertical orientation on a separate $8\frac{1}{2} \times 11$-inch page. The points along the sensations scale were marked with numbers, and the points along the distress scale with numbers and verbal labels of distress magnitude. Instructions for rating sensation and distress were the same as Johnson's (1973).

Following the instructions, the subject was told to put his hand in the water and to make sensation and distress judgments whenever the tape indicated. The signals for making the ratings were given 10, 35, and 60 sec after the subject immersed his hand in the water, every 30 sec thereafter for 4 additional judgments, and then once every minute until a 6-min. period had elapsed (10 judgments in all).

The subject was then asked to remove his hand from the water and to continue to make sensation and distress judgments when asked. A total of 6 postimmersion judgments were made beginning 15 sec after the subject removed his hand from the water and continuing at 30-sec intervals for a $2\frac{1}{2}$-min. period. The experimenter returned to take the last blood pressure reading, and the subject completed another MACL.

Postexperimental questionnaires. Following the completion of the MACL, the subject was taken to another room to complete a series of questionnaires that asked about each of the sensations, arousal cues, and procedural events mentioned in the instructions along with questions on other sensations and feelings not mentioned. All items used 20-point Likert scales.

A final MACL was administered, along with a self-esteem questionnaire and a postexperimental questionnaire that asked about thoughts, feelings, and methods the subject used to adapt to stress during the immersion period. Halfway through the questionnaires, the subject was offered his choice of coffee, tea, coke, or milk for a short break. A thorough debriefing completed the procedure.

Results

Manipulation Checks

The postexperimental questionnaire checked on the effectiveness of the manipulations. For each of the 12 sensations mentioned in the sensory message, each of the 12 arousal signs mentioned in the arousal message, and each of the various events mentioned in the procedural information message, the subject was asked to make ratings with respect to the following four questions: (a) How strongly was it expected? (b) How strongly did he remember being told to expect it? (c) How strongly was he aware of the sensation, sign, or event? and (d) How closely did his experience match his expectations? Several other items were included on the questionnaire, and they will be mentioned when results are reported.

Information manipulations. Overall means of subjects' responses to the 12 sensory and the 12 arousal questions are presented in Table 1. Compared to subjects in the other conditions, subjects in the sensory information condition recalled being exposed to the sensory information, $F(2, 44) = 69.26$, $p < .001$, and reported stronger expectations that they would experience these specific sensations, $F(2, 44) = 5.54$, $p < .05$. Subjects given arousal information recalled being exposed to that information, $F(2, 44) = 45.50$, $p < .001$, but when compared to other subjects they did not report significantly stronger expectations that they would experience these arousal symptoms, $F(2, 44) < 1$, $p > .25$. Finally, subjects in the high pain-magnitude conditions recalled being told to expect strong pain, $F(1, 44) = 9.10$, $p < .005$, and reported stronger expectations that they would feel pain than did subjects in the no-pain condition, $F(1, 44) = 7.21$, $p < .01$.

The results are very clear in showing that subjects remember what they have been told. But they also show that what subjects have been told is not always equivalent to what they expect. The high-magnitude pain warning clearly produced differences in expectations for experiences of pain. The sensory information was also reasonably effective in producing differences in expectations regarding these experiences. The one exception to this was the relatively high expectation of sensations for the subjects in the high-magnitude pain warning control condition. The overall mean of the 12 items measuring expected sensations for this group was high be-

Table 1
Mean Responses by Condition for Questions on Sensation Information and Behavioral Arousal Information

Warning	Information	Remember	Expect	Awareness	Match
		Experimental condition			
		Sensation information questions			
High pain warning	Sensation	14.682	12.773	13.000	14.180
	Arousal	2.377	9.195	12.140	13.180
	Control	3.875	11.125	12.180	13.190
No pain warning	Sensation	13.404	11.980	10.270	13.050
	Arousal	4.586	8.838	11.130	12.940
	Control	2.111	9.040	10.270	14.840
		Behavioral arousal questions			
High pain warning	Sensation	2.830	7.568	6.977	14.190
	Arousal	13.455	7.091	6.455	12.690
	Control	1.568	8.102	8.170	14.140
No pain warning	Sensation	3.091	5.687	6.545	13.510
	Arousal	10.566	6.828	8.020	11.700
	Control	2.404	6.054	5.323	15.530

Note. Scores can range from 1 to 20.

cause the high-magnitude pain warning produced a pronounced elevation in three of the expectation items: (a) expected coldness, (b) expected stiffness of the fingers, and (c) expected pinpricking sensations. Each of these questions refers to a sensation known to be associated with severe cold, and the pain warning seems to have alerted subjects to expect these symptoms. Finally, the data suggest that arousal information, although clearly remembered, failed to provide any strong expectation or set for the subjects.

There are two reasons for caution in interpreting the effects of the instructions on subjects' expectations. First, the responses are retrospective reports given after the subjects had been exposed to the cold water stimulus, and we do not know whether the reports at this point would correspond precisely to reports given prior to exposure. For example, it is possible that expectations immediately prior to exposure are more precise, clear, or certain in informed than in uninformed subjects. Second, there is no reason to assume that expectations will have the same effect on later behavior if they are based in one instance on information from the experimenter (sensory informed) and in another instance on information provided by the subject himself (e.g., high-magnitude or pain warning control subjects).

Table 1 also indicates that the preparatory information did not produce suggestion effects, since there were no significant differences between conditions on awareness of sensation or arousal signs. There also were no differences between conditions in reported matches between experience and expectations. But we cannot assume that subjects in different conditions were equally attentive to the sensory experiences and arousal signs, since the question merely asks if the signs were noticed. Similarly, we do not know if the reported match of experience and expectations in unprepared subjects was a postexperimental conclusion saying, "Yes, I guess that was what I did expect," and for prepared subjects was a conclusion during immersion saying, "Yes, I'm feeling just what they told me to expect."

Response to Stressor Impact

Four major dependent measures were obtained during exposure to the noxious cold pressor stimulus: distress ratings, strength-of-sensation ratings, finger temperature, and heart rate. Though there were changes in heart rate over time, the average 2 beats/minute increase during instructions and the average 8–12 beats/minute decrease during immersion being statistically significant, there were no significant treatment differences. Thus, the heart rate data will not be reported or discussed further. Reports of trial effects are omitted, since they are all highly significant.

Distress ratings. Figure 1 presents the 10 distress ratings for the sensation, arousal, and control conditions in high-magnitude pain warning conditions, and Figure 2 presents the same data for the low-magnitude (no pain warning) conditions. It is immediately obvious that distress increased quite sharply during the first minute and a half (the first four judgments) of exposure and then leveled off. But distress reporting was not identical across the three conditions; the sensory information group showed a precipitous drop in reported distress, beginning with Judgment 6 ($2\frac{1}{2}$ min.), in the no pain warning conditions. The decline in distress is far smaller and begins somewhat later, at Judgment 7 (3 min.), in the high-magnitude pain warning condition. The difference between the three types of condition is reflected in a highly significant interaction between treatments and judgment trials, $F(18, 396) = 3.44$, $p < .001$.

It is obvious from the pattern of findings that treatment effects became manifest only during the final 4 min. of immersion; all groups acted similarly during the first 2 min. of cold water impact. Separate planned comparisons were run on Judgments 5 through 10. Subjects in the sensory information groups reported significantly less distress than did subjects in the control conditions, $F(1, 229) = 24.49$, $p < .001$, and the sensory-informed subjects also reported significantly less distress than did subjects in the arousal information groups, $F(1, 220) = 9.76$, $p < .001$. The level of distress reported in the arousal information groups did not differ from that in

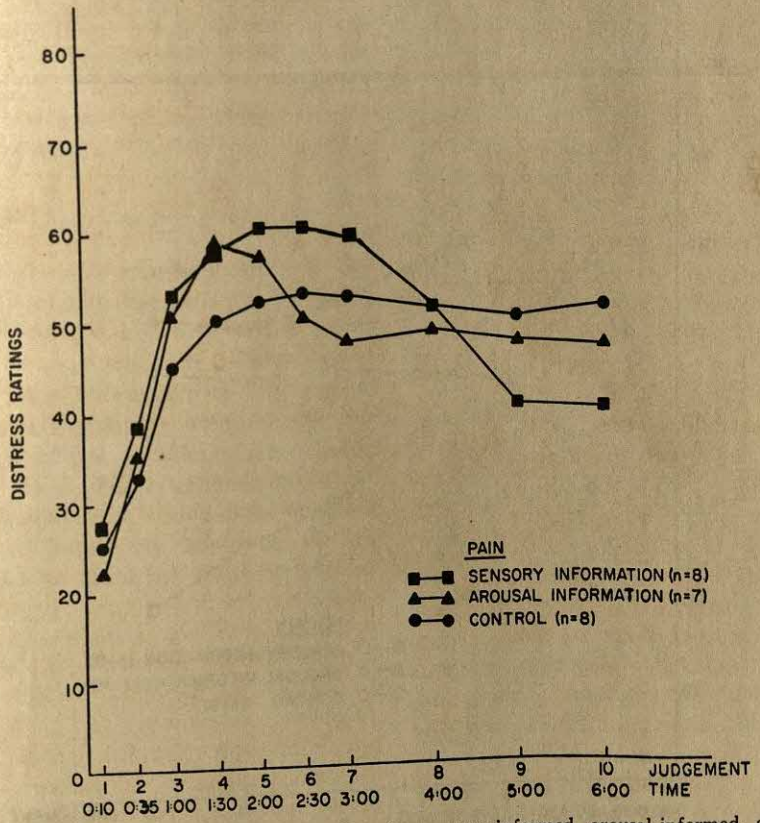

Figure 1. Ratings of distress during immersion for sensory-informed, arousal-informed, and control conditions with high-magnitude pain warning—Experiment 1.

the control conditions. These tests show that sensory information significantly reduced distress during the final judgments (last 4 min. of immersion) in relation to both control (procedural) and arousal information, while arousal information had no substantial affect on distress reduction.

The final critical comparison is between the sensory information group with no pain warning and the sensory information group with the high-magnitude pain warning. If the pain warning blocked distress reduction by sensation information, it would support the processing notions and lead us to reject the simpler version of the accuracy hypothesis. A separate analysis of variance of the last judgments, 5 through 10, for these two conditions (sensation – high pain vs. sensation – no pain) yielded a nearly significant main effect, with less overall distress reported in the no pain warning – sensation group, $F(1, 15) = 4.29$, $p < .06$. The reduction of distress in the sensory information group with no pain warning (M decrease $= 34.12$) was greater than that in the sensory information group with the high pain warning ($M = 20.97$), but the overall interaction of pain warning with trials was not significant, $F(5, 75) = 1.84$, $p < .15$. Given the virtual identity in rated distress for the first five trials, it appears that the pain warning interfered with distress reduction in the final 3½ min. of exposure.

Sensation ratings. Sensory information was expected to change distress ratings but to have no effect on the reported strength of sensations. The data showed, however, a greater drop in the rated strength of sensations in the sensory information groups than in the control groups and low ratings in the arousal information – no pain warning condition. This produced a significant Condition × Trials interaction, $F(18, 396) = 3.98$, $p <$

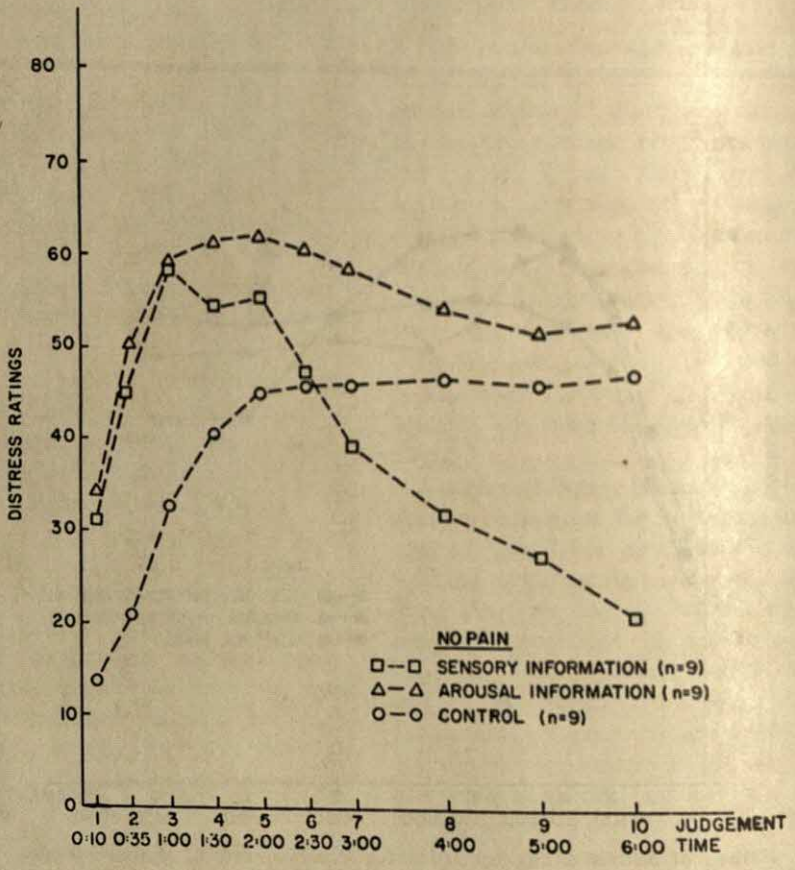

Figure 2. Ratings of distress during immersion for sensory-informed, arousal-informed, and control conditions with no pain warning—Experiment 1.

.001. Despite this effect, the condition differences were smaller than those for distress ratings, and there was no difference between the sensory information – high-magnitude pain warning and sensory information – no pain warning conditions. It is possible that both distress and sensation ratings changed in similar ways because subjects failed to discriminate sharply between them, but the more substantial impact of sensation information on the distress ratings suggests that the differentiation was made by at least some of the subjects. Separate figures are not reported for the sensation data because of their basic similarity to the distress findings.

Finger temperature. Figure 3 presents the finger temperature readings for all six experimental groups at 10 different times during the final 3 min. of cold water immersion. Finger temperatures for the first 3 min. were excluded from the figure and analyses becaus Teichner's (1965) findings showed the latenc of vasodilation to be in the neighborhood 240 sec. It is immediately obvious from Fi ure 3 that the no pain warning – sensory i formation condition shows a distinct rise skin temperature. The difference between t 3- and 6-min. finger temperature was co puted for subjects in all six conditions, a a planned comparison showed significant greater increases in skin temperature for su jects in the sensory information – no pa warning conditions than in the other five co ditions, $F(1, 342) = 41.31$, $p < .001$, a greater increases in skin temperature for t sensory-informed – no pain warning group comparison to the sensory-informed – hig magnitude pain warning group, $F(1, 342)$ 15.83, $p < .001$. The temperature data pr vide support for the hypothesis that senso

information reduced distress only in the absence of pain warnings—a prediction following from the view that processing the stressor input as objective rather than as subjective emotional information is the critical factor in distress reduction.

Postimmersion Questionnaire Responses

The postimmersion questionnaire was designed to help clarify the processes underlying the treatment effects. Significant results were found for one of two sets of questions, a 3-item scale that attempted to assess subjects' strategies for coping with the distress experience (Kanfer & Goldfoot, 1966). This scale focused on the subject's tendency to develop an "objective set" toward the noxious stimulus: (a) "While my hand was in the water, I tried to think of it as something separate from me, so that I was not actually experiencing the discomfort, but rather, my hand was"; (b) "When my hand was in the water, I tried to think of the whole experience as something which would be informative and interesting to observe"; (c) "While my hand was in the water, I tried to concentrate on all the sensations that it was experiencing—sensations such as tingling, pinpricking, etc." As can be seen in Table 2, subjects receiving sensory information gave significantly higher ratings to these items than arousal information or control subjects, $F(1, 44) = 4.38$, $p < .05$. This did not happen because sensory-informed subjects agreed to Item 3, since the second item (informative and interesting to observe) was the best single discriminator of the groups, $F(1, 44) = 4.90$, $p < .04$.

Four other significant findings suggested that both sensation and arousal information

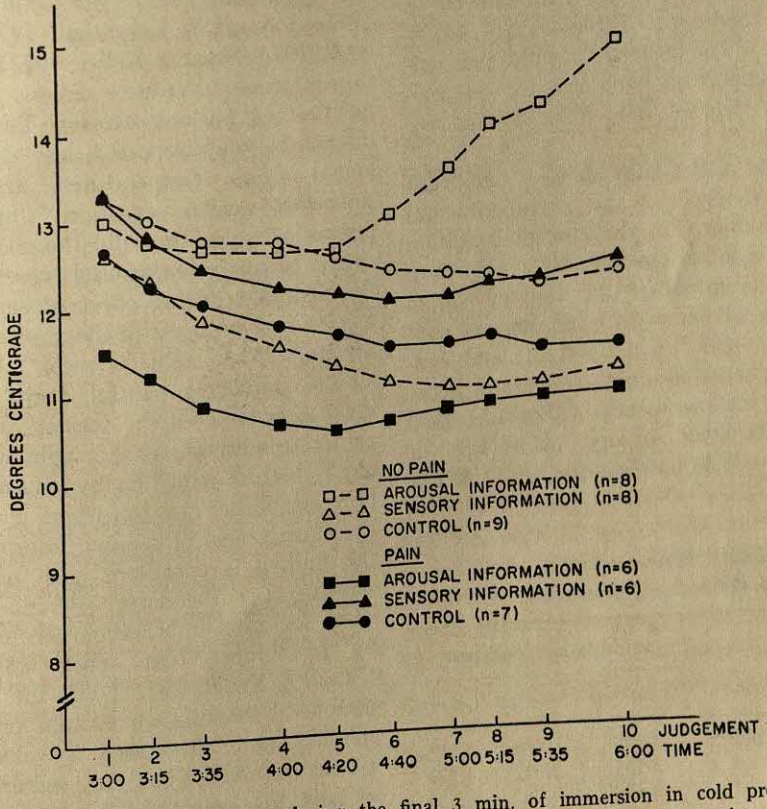

Figure 3. Skin temperature readings during the final 3 min. of immersion in cold pressor for sensory-informed, arousal-informed, and control conditions, both with no pain warning and pain warning—Experiment 1.

Table 2
Self-Ratings on Objective Set Items

Warning condition	Information condition		
	Sensation	Arousal	Control
High pain warning	7.417	5.048	6.458
No pain warning	7.074	5.148	5.074

Note. Scores can range from 1 to 15.

affected emotional states. First, when asked if they had "thoughts and worries about how the cold water might damage your hand," subjects in the arousal information condition reported significantly *less* worry than did subjects in either the sensory or the control group, $F(1, 44) = 4.57$, $p < .05$ (see Table 3). Second, on a postexperimental questionnaire measure of avoidance motivation, subjects in the arousal condition reported less desire to remove their hand from the cold water during the immersion period than subjects in the control conditions (Table 4), $F(1,44) = 4.32$, $p < .05$. The postexperimental questionnaire data support the hypothesis that arousal-informed subjects will show reduced avoidance motivation.

Two mood scales also showed significant treatment differences on the postexperimental measures: Subjects in the control condition were more tense and anxious ($M = 6.5$) than were subjects in either the *sensory* ($M = 2.2$) or arousal ($M = 3.2$) information conditions, $F(1, 43) = 8.26$, $p < .01$, and control subjects reported a greater sense of hopelessness and defenselessness ($M = 4.5$) than did subjects given sensory ($M = 1.6$) or arousal ($M = 2.3$) information, $F(1, 43) = 7.85$, $p < .05$. These differences appeared only in the high-pain warning conditions and only for the postexperimental (post-cold pressor) measures; there were no significant differences on the mood scales given prior to the cold pressor treatment.

Table 3
Means of Subjects' Reports of Thoughts and Worries

Warning condition	Information condition		
	Sensation	Arousal	Control
High pain warning	5.625	1.857	9.125
No pain warning	3.111	2.222	4.222
M	4.294	2.062	6.259

Note. Scores can range from 1 to 15.

Table 4
Means of Subjects' Reported Desire to Remove Their Hand from the Water

Warning condition	Information condition		
	Sensation	Arousal	Control
High pain warning	13.50	8.86	15.38
No pain warning	10.11	8.89	12.44
M	11.71	8.88	13.82

Note. Scores can range from 1 to 20.

Discussion

The results lend clear support to past findings (Johnson, 1973, 1975; Johnson et al., 1975; Johnson & Leventhal, 1974; Johnson et al., 1973; Staub & Kellet, 1972) that sensation information reduces distress during contact with a noxious stressor. The sensation-informed group reported less distress, had higher finger temperatures, and reported somewhat weaker sensations from the cold pressor stimulus than did the control groups or the groups given arousal information. But the distress-reducing effect of sensory information was strongest in the absence of a pain warning. When subjects were told that the stressor was very painful, there were small differences between the sensory, arousal, and control conditions. That a pain warning can block distress reduction by sensory information establishes an important limitation on the effectiveness of sensory information. And the finding is consistent with prior studies showing (a) increased tolerance of shock when sensation information was accompanied by reassurance that shock was harmless (Staub & Kellet, 1972); (b) the blocking of peripheral vasodilation to cold pressor when subjects were threatened by electric shock (Teichner, 1965); and (c) increased reports of pain to electric shock when the subjects were given a pain warning (Hall & Stride, 1954).

The findings suggest that a simple accuracy hypothesis does not readily account for the pain-reduction effects of sensory information and indicate that different kinds of preparatory information alter the way the noxious stimulus information is processed to change the subject's experience of the stressor. Sensory information leads to an objective, nonaffective experience of the stimulus; magnitude information, or a pain warning, leads to an emotional experience of the stimulus. When objectively processed, the noxious input is coded or categorized in terms of specific sensory features, such as coldness, numbness, pins and needles, and so forth, and emotional distress reactions habituate. When emotionally processed, the information is encoded or integrated in an emotional schema or pain memory (Engel, 1959; Leventhal & Everhart, in press), and the stimulus and coding continue to stimulate distress.

The hypothesis that the pain warning activates an emotional pain memory for the encoding of the noxious experience of the cold pressor suggests that the warning might convert each of the sensation cues into a series of threat cues; Epstein (1973) offers a similar interpretation of the effects of pain warnings for subjects' responses to successive numbers in response to a loud noise presented during a sequential countdown procedure. Correlations between heart rates and the number of sensations expected by subjects (measured by the 12 items in Table 1) support this expectation in the present data. Sensation-informed subjects who received a pain warning showed higher heart rates the more sensations they expected ($rs = .16$ to $.62$ for the nine heart rates recorded during immersion), whereas sensation-informed subjects who *did not* receive a pain warning showed lower heart rates the more sensations they expected ($rs = -.46$ to $-.67$ for the nine heart rates recorded during immersion).

Other features of the data support the idea that sensation information leads to an objective or nonthreatening schematization of the stimulus, which then facilitates habituation of distress. First, the subjects given sensation information clearly adopted a more objective, detached set toward the exposed hand. While this finding held whether or not the subjects received a pain warning, the sensation-informed subjects given a pain warning also reported considerable worry about the noxious event; the objective schematization would be in competition, therefore, with an emotional representation of the experience that would be distress stimulating. Second, it is also clear that sensation information produces its effects gradually; the conditions all reached approximately equal peaks of distress at $1\frac{1}{2}$ min. after immersion, and differences between conditions were clear only during the latter $3\frac{1}{2}$ min. of exposure. And while the data were not as clear as we might like, it is reported distress rather than reported strength of sensations that shows the more pronounced decline during this final period, and increased hand temperature (for sensation-informed – no pain warning subjects) follows approximately 2 min. after the beginning of the decline in distress reports. It would appear, therefore, that the acquisition of an objective schema of the noxious stimulus facilitates the habituation or reduction of distress, and this in turn reduces the sympathetic discharge that sustains peripheral vasoconstriction (Teichner, 1965).

Arousal information had relatively little impact on reports of stimulus strength or distress during stimulus impact. It did, however, sharply reduce past experimental reports of worries, thoughts of harm, and reported desire to remove one's hand from the water. Thus, being aware of and expecting a host of bodily reactions seems to have reduced the level of fear and avoidance motivation stimulated by the noxious stimulus sensations and distress. And these effects occurred even though all subjects, arousal-informed or not, expected these responses. Thus, being told about them by the experimenter appears to be a form of reassurance, perhaps, because it suggests that one is responding as do other subjects and need not be threatened or worried by one's reactions. This outcome is compatible with Calvert-Boyanowsky and Leventhal's (1975) interpretation of the misattribution studies.

Experiment 2

Experiment 1 suggested that sensory information reduced distress because it altered the way subjects processed the noxious input; it prepared the subjects to generate an objective schema of the stimulus features, which facilitated the habituation of distress. An alternative interpretation of this effect is that the act of analysis itself and its accompanying "distancing" of the self from stimulation, rather than schematization of the noxious event per se, is the critical factor in distress reduction. Analysis of features may create an attentional set inconsistent with the holistic, integrative set that seems to be necessary for the integration of stimulus perception and bodily reactions into an emotional experience (Blitz & Dinnerstein, 1971; Krueger, 1928; Leventhal, in press; Schachter & Singer, 1962). Emotional experience is described as holistic at a phenomenal level (Krueger, 1928), and experimental data show that analytic sets disrupt emotional experiences associated with positive, humorous stimulation (Cupchik & Leventhal, 1974; Leventhal & Cupchik, 1976).

The considerations discussed above suggested a simple study in which subjects were assigned to one of three conditions: (a) an attention set, in which subjects were asked to monitor the site of impact (i.e., the experiences they were having in their hand while it was in the cold water; (b) an attention-to-hand-and-body set, where subjects were asked to monitor both their hand and their body reactions to the stressor; and (c) an uninstructed control group.

The comparison of attention to hand and body to the control condition and to the attention-to-hand-alone condition would allow us to evaluate a variety of alternative hypotheses. If subjects in the combined attention-to-hand-and-body condition reported less distress than subjects in both control and attention-to-hand-only conditions, it would support the idea that focusing attention on all details of the situation is distress reducing (i.e., that an analytic set and coding of specific features is distress reducing). This outcome also would seem plausible if one believed that a combination of sensation and body information would allow for maximal preparation.

If objective schematization of the input is the critical factor in distress reduction and habituation, it would be essential for the subject to monitor the site of cold pressor impact, and it would be most efficient for schema formation if he paid exclusive attention to the objective features of stimulation to the hand. Assuming that the formation of an objective schema of the input is necessary for habituation also suggests that attention to the hand should produce a decline in distress during the latter 3½ to 4 min. of exposure to the noxious stimulus. This hypothesis assumes that sensation information affected distress in Experiment 1 because it encouraged schematization of objective stimulus features by focusing attention on them. This reasoning is supported by Epstein's (1973) finding that habituation to simple tones occurs only when the subject directly attends to them. When attention is directed elsewhere, there is no habituation to the tones.

Method

Subjects and Design

A total of 68 right-handed males volunteered for this study. All were enrolled in introductory psychology classes at the University of Wisconsin–Madison and received class credit for participation. Five were disqualified because of health problems; six asked to be excused from participation during the cold pressor task; and one subject was dropped because of extremely atypical behavior before the experiment. The remaining 56 subjects were randomly assigned to the three conditions: (a) attention to hand only, (b) attention to hand and body, and (c) control.

Procedure

The subject was seated comfortably in an armchair and heard the introductory instructions over a loudspeaker. These instructions explained the procedure for the attachment of a thermistor measuring hand temperature and assured the subject that the cold pressor treatment would be harmless. Each subject completed a medical questionnaire, to screen out people with health problems. The subject then read and signed a voluntary consent form that indicated that he could quit the experiment without losing credit for participation. All subjects initially agreed to take part in the study. The thermistor was

then attached to the middle finger of the subject's right hand, and the experiment proceeded as follows.

Stress task. Two insulated water tanks were located to the right of the subject—one with water at room temperature and the other with cold water. The room-temperature tank (22 °C) was used to be sure of a common initial hand temperature for all subjects. The cold water was maintained at a constant temperature of 7 °C by a circulating pump that sent the water through an auxiliary ice bucket. Before leaving the room, the experimenter asked the subject to immerse his right hand in the room-temperature tank. The remainder of the instructions were heard over a loudspeaker.

Distress ratings. The instructions for rating distress were identical for all the groups. Subjects were told:

> While your hand is in the cold water, you will be asked to record your judgment on the scale of distress. The distress scale . . . refers to the amount of upset or distress the sensations cause. Zero . . . means you are feeling no upset or bother at all. One hundred means the maximum amount you can imagine of the upset or distress you will experience.

The subject was told to make his judgments when the word *judgment* was said in the tape-recorded instructions. He was told to "say the number on the scale which most accurately describes how you feel at that moment. . . . Each judgment is independent of previous ones. That means your ratings may go up, down, or stay at the same level."

Attention instructions. At this point, the experimenter randomly selected a ballot to assign the subject to one of the three conditions and played back the appropriate instructional tape for that condition. In the attention-to-hand-only condition, the subject heard the following instructions:

> During the time your hand will be in the colder water, you will feel many sensations in your hand. The sensations will change over time. We would like you to pay attention to the sensations or feelings in your hand only, so that you will be able to describe each of the specific feelings and sensations that you experienced. I will ask many questions about the different sensations in your hand afterwards, and this is the most important part of the study. So ignore everything else and pay close attention to the sensations in your hand.

In the condition for attention to hand and body, subjects heard the same instructions, with the exception that the phrase ***hand and body*** was inserted for ***hand***. The control group did not get any of the manipulation instructions.

Distress ratings. The recording then asked the subject to move his hand to the cold water tank and called for the distress judgments. The subject made 13 distress ratings—9 during the 6 min. of the cold pressor task and 4 after removing his hand from the water. The first judgment was requested 10 sec after immersion in the cold water; 2 additional judgments were then requested at 25-sec intervals, and the interval was expanded to 50 sec for the remaining judgments. Six minutes after he placed his hand in the cold water, the subject was instructed to remove it, and 4 additional judgments were requested at 30-sec intervals. The subject made his ratings by calling out a number from 0 (not at all) to 100 (maximum) on the 100-point distress scale.

Distress judgments were the only judgments called for in this experiment and in Experiment 3. Interviews with pilot subjects showed that it was more difficult for them to make the distinction between distress and sensation than in Experiment 1, a difficulty that could stem from the absence of sensation instructions that helped the subjects in Experiment 1 focus more clearly on particular sensory features. Use of a pain rating was rejected, since mentioning the word *pain* prior to cold water immersion might obliterate distress reduction and treatment differences.

Finger temperature. Finger temperature was recorded on a meter located in the control room. The first temperature recording was made while the subject's hand was in the room-temperature tank, and three additional recordings were made, one at each of the distress ratings.

Postexperimental questionnaires. At the close of the procedure, the experimenter removed the thermistor and gave the subject two questionnaires. The first was a sensation and feature checklist asking the subject to rate (on a 21-point scale) the degree to which he noticed various sensations in his hand ("hand throbbing" or "tingling, biting sensations in fingers"), sensations in his body ("speeded-up breathing" or "feeling as if your body is exerting a great deal of effort"), and various features of the environment (e.g., instructions, procedure, and room).

The second questionnaire included direct questions about the percentage of the time the subject focused his attention to his hand and to his body. The subject made these judgments with reference to each of three time periods—the beginning, middle, and end of the cold pressor task. Thus, there were three questions for attention to hand and three for attention to body. The second questionnaire also included a question inquiring about the level of tiredness and tenseness that the subject felt toward the end of the immersion episode. At the conclusion of the session, the subject was debriefed, and the experimenter answered any of his questions about the study.

Results

Distress Ratings

Separate analyses were conducted on the 9 impact ratings given during the exposure to the cold water and the 4 recovery ratings given after the hand was removed from the

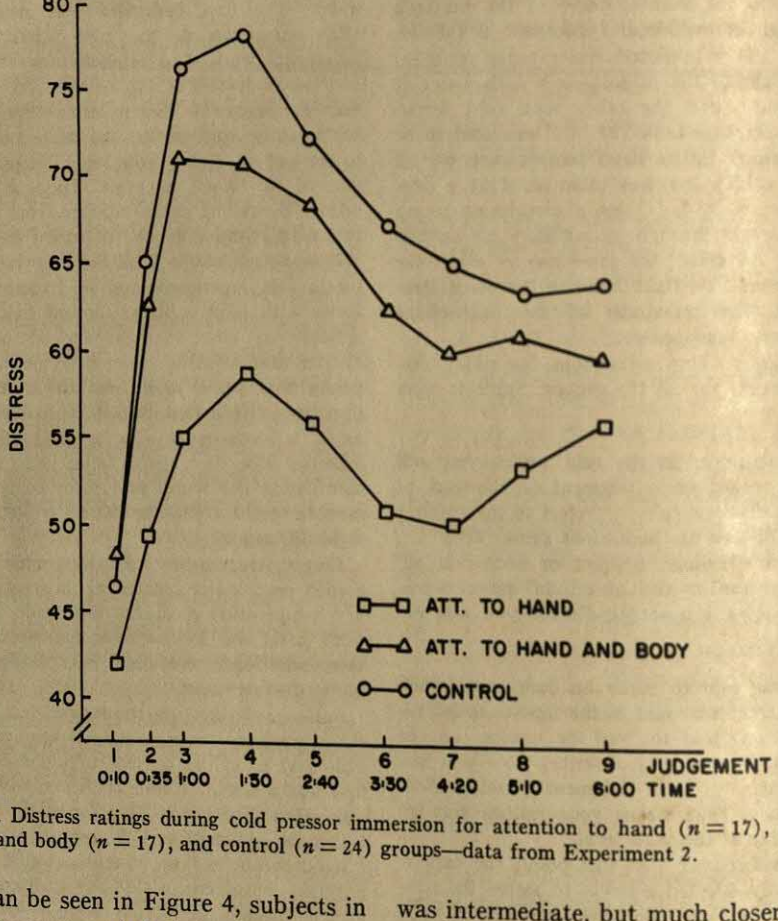

Figure 4. Distress ratings during cold pressor immersion for attention to hand ($n = 17$), attention to hand and body ($n = 17$), and control ($n = 24$) groups—data from Experiment 2.

water. As can be seen in Figure 4, subjects in all three groups reported sharp increases in distress during the first minute of immersion (Judgments 1 to 3), which peaked at Judgment 4 and then leveled off and dropped slightly during the remaining time the hand was in the water. As can also be seen from the figure, the groups began at the same level, but the rate of distress increased very much more rapidly in both the control and attention-to-hand-and-body conditions, so that by the second judgment these two groups were at substantially higher levels of reported distress than the attention-to-hand subjects, and the difference remained at relatively the same magnitude throughout the 6-min. period.

The component of the main effect that tests the hypothesis that attention-to-hand subjects are less distressed ($M = 52.99$) than control subjects ($M = 66.68$) is statistically significant, $F(1, 55) = 4.45$, $p < .05$. The attention-to-hand-and-body group ($M = 61.96$) was intermediate, but much closer to the control than to the hand-only condition, and separate tests show that it did not differ significantly from either the hand-alone, $F(1, 55 = 2.12$, *ns*) or the control condition, $F(1, 55 = .58$, *ns*). Finally, there is no significant Treatment × Trials interaction.

Recovery Ratings

Although distress declined sharply during the recovery phase, there were no treatment differences.

Finger Temperature

There were no significant treatment differences or interactions of treatments with trials. The failure to find effects may be due in part to the change in water temperature (2 °C in Experiment 1, 7 °C in Experiment 2), difficulties with the temperature meters and elec

trodes, and factors related to the time of year at which the data were collected.

Postexperimental Questionnaire Reports

Awareness. Subjects estimated the amount of attention they paid to their immersed hand during the beginning, middle, and end of the 6-min. immersion in the cold water and the amount of attention they paid to their body reactions during each of these same three periods. These ratings were made on 11-point scales ranging from 0% to 100% of attention. Subjects also completed a checklist on which they rated the degree to which they felt each of 35 sensations (1 = not at all aware of it, 21 = very strongly aware of it). Eight of these items related to the hand only, and 11 to the body reactions only. The remaining 16 items focused primarily on attention to situational factors such as the procedure.

Significant treatment effects appeared on both measures: Subjects in the attention-to-hand-and-body condition reported paying a greater percentage of attention to their body reaction ($M = 32.05\%$) than did subjects in either the attention-to-hand-only condition ($M = 17.35\%$) or the control condition ($M = 14.82\%$), $F(2, 100) = 5.68$, $p < .01$; the control and attention-to-hand-and-body conditions were not significantly different. Subjects in the attention-to-hand-and-body condition also checked greater awareness of specific body reactions ($M = 79.7$); the control group was intermediate ($M = 59.5$); and the least aware were subjects in the hand-only condition ($M = 39.4$), $F(2,47) = 5.77$, $p < .01$. Each of the groups was significantly different from the others at the .05 level by t test. There were no significant treatment effects for the measures of attention to the hand.

Fatigue. On three 21-point scales, subjects responded to the following items: "Toward the end of the time your hand was in the water, did you feel (a) tired, (b) tense and jumpy, (c) detached and daydreamy?" Subjects instructed to attend to their hands only reported lower levels of tiredness ($M = 2.86$) than was reported by subjects instructed to attend to hand and body ($M = 6.4$) or by control subjects ($M = 5.6$), $F(2, 42) = 3.94$, $p < .05$.

Discussion

Attention to the site of stressor impact, the hand only, reduced levels of reported distress during cold pressor. Instructions to attend to both hand and body did not, however, produce statistically significant effects. Thus, the mere act of selectively deploying attention and analyzing the stimulus field is not sufficient for distress reduction; focusing of attention on the site of stressor impact is critical for distress reduction, through a habituation-type process.

While the data are generally supportive of a processing interpretation (i.e., that lower levels of distress and reduced tiredness are due to the formation of an objective schema of stimulus properties and the habituation of distress), there is one feature of the data that is not fully consistent with this interpretation: The differences between conditions should have been greatest toward the 3rd and 5th minutes of the immersion period, rather than during the 1st minute, as shown in Figure 4. The data suggest that the conditions differentiated very rapidly, and this was reflected in the analysis, which found a main effect between conditions but no Treatment × Trials interaction. A second problem was the failure to detect differences between conditions in the measure of the percentage of time subjects reported that they attended to their hand. Indeed, control subjects reported having attended as much to their hand as did attention-instructed subjects. Postexperimental interviews suggested that this attention was not the same. For the control subjects, the attention seemed automatic, involuntary, and stimulus engendered; they could not ignore the distress of the stimulus impact. For the instructed subjects, attention seemed self-engendered, controlled, or voluntary, a deliberate focusing of awareness on stimulus properties. Indeed, a comparison of findings and impressions from the postexperimental interviews of Experiments 1 and 2 suggests that sensation information may be superior to direct attentional instructions, in reducing distress, since the former defines the stimulus features to be monitored and provides schemata to be used in coding the input (Bruner, 1957).

Experiment 3

Experiment 3 was designed to obtain better evidence with respect to the effects of the attentional instructions on the cues subjects monitor and to provide a better test of the hypothesis that schematization of the stimulus preceded distress reduction and habituation. Evidence on the deployment of attention was obtained by introducing a specific distractor to direct attention in the control condition. Evidence was obtained for the assumption that objective schema formation precedes reductions in distress by systematically varying the deployment of attention during the early and later parts of the cold water immersion. The strength of sensations and distress from the cold pressor stimulation begin at relatively low levels and gradually build in intensity. It should be relatively easy to direct attention to and schematize stimulus features at this time. As the stimulus becomes more intense, the schema should be reinforced by repetition of the features detected earlier. On the other hand, subjects instructed or motivated (by threat) not to attend to the stimulus may have difficulty deliberately directing their attention to stimulus features if they are first instructed to monitor the stimulus later in exposure. Delaying attention and permitting the stimulus to build to maximum strength, to be integrated with pain memories, and to be experienced as a distressing event will make it difficult to monitor and schematize, since the pain and distress may block attention to specific features.

The assumptions mentioned above are generally compatible with empirical observations made on studies of behavior and neural habituation in the cat (Groves & Thompson, 1970). Habituation occurs more rapidly to stimuli that increase gradually in strength early in a series of stimulus exposures, and habituation is relatively slow and sometimes fails to occur for strong stimuli. To test the assumption with cold pressor, a four-group experiment was designed varying attention to and distraction from the hand at different times during immersion in ice water. In one condition subjects were instructed to monitor the hand throughout the immersion period (attention–attention). In a second condition (attention–distraction) they were instructed to monitor the hand for the first half of the immersion period, during the time of increasing strength of sensations when schema formation is critical, and they were distracted by slides in the second half. In a third group (distraction–attention) subjects were instructed to attend to and monitor the hand for the last half of the immersion period after the input had presumably been classified and responded to as painful, thus blocking the positive effects of monitoring. A fourth group (distraction–distraction) was distracted for the entire immersion period. The hypothesis under test was that monitoring throughout the immersion period and monitoring during the first half of the immersion period would be equally effective for schema formation and would facilitate habituation during the second half of exposure. Monitoring during the last half of immersion and continual distraction should be equally ineffective for distress reduction.

Method

Subjects

Seventy-six male undergraduates at the University of Wisconsin served as subjects. They were selected from a larger pool of subjects, and before being permitted to participate, they were screened and excluded if they reported a health problem (e.g., a history of diabetes, rheumatic fever, heart abnormality, or high blood pressure) or if they were left-handed. An incentive of $2 per hour was offered to encourage participation. Nine subjects quit during exposure to the cold water treatment (they did not cluster in any particular condition), and one refused to participate when told about the noxious stimulus. Two subjects were dropped, one because he was hard of hearing and did not hear all of the instructions and another because he meditated during the experiment. The 64 subjects who remained were randomly assigned to one of the four conditions with the restriction that a subject was assigned to each of the four conditions before assignment was begun to another replication. This procedure was repeated eight times for each of the two male experimenters.

Distraction Materials

In postexperimental interviews for Experiment 2 subjects suggested that it was difficult to distract

themselves from their hand in the absence of an alternative stimulus. For this reason, 48 color slides of landscapes and people were used as distractors throughout the nonattention condition of Experiment 3, and 24 of the slides were used as distractors for the late and early nonattention (distraction) periods of the early and late attention conditions.

The 48 slides were selected from a larger set of 250. The experimenter first eliminated those slides suggesting pain or coldness (e.g., winter landscapes, scenes including water, etc.). The 60 slides remaining after this elimination were then shown to a group of six males and six females who had previously been exposed to the cold water stimulus and who rated them as to how much they thought the slide could distract them from the (cold pressor) pain. The 15 slides having the highest mean score (none scored less than $M = 4.75$ on a 7-point scale where 1 = attends to the pain and 7 = distracts from the pain) were selected as distraction stimuli and were used as standards for the selection of 33 additional distractors from yet another set of slides. The additional slides were matched to the first 15 in subject matter and amount of detail. We can best characterize these slides by saying that they were sufficiently interesting to attract attention and prevent deliberate monitoring of the hand, yet not so interesting as to provoke a strong alternative emotional response that would compete with the emotional distress evoked by the noxious stimulus.

Procedure

The procedure was virtually identical to that in Experiment 2. One major change was to raise the temperature of the laboratory to 26 °C and the temperature of the water used to establish a common baseline to 30 °C. It was hoped that these changes would facilitate recording skin temperature change.

The subjects in each of the four conditions went through the same seven steps in the following order: (a) completion of the medical screening questionnaire and reading and signing the consent form; (b) listening to an overall description of the aim and procedure of the study; (c) immersing the right hand in the warm (30 °C) water; (d) hearing an explanation of the distress rating scale and the rating procedure; (e) receiving attention and/or distraction instructions appropriate for the experimental condition; (f) removing the hand from the warm water and immersing it in the cold water (7 °C) for 5 min. and 15 sec; (g) removing the hand from the cold water tank and making judgments of distress at specified times during a 2-min. postimmersion period. The exact times for judgments and so forth are presented later on.

Attention instructions. The attention–distraction instructions for each condition were presented after the description of the distress rating procedure. Subjects assigned to the attention–attention condition heard the same attentional instruction as that given in Experiment 2. The instructions for the distraction–distraction group differed from those in Experiment 1, since slides were used as distractors in the current study. The instructions were as follows:

> During the time your hand will be in the cold water, you will see landscape and art slides. We would like you to pay attention to these slides, so you will be able to answer questions about them afterwards. This is the most important part of the study, so ignore everything else and pay close attention to the slides.

The instructions were modified somewhat when combined for the attention–distraction condition, and their order was reversed for the distraction–attention condition. The instructions were as follows:

> The time your hand will be in the colder water is divided into two parts. In the first part, we would like you to pay close attention to the sensation in your right hand so that you will be able to describe each of the specific feelings and sensations that you experienced. You will be asked many questions about the different sensations in your right hand afterwards. In this part try to ignore everything else and pay close attention to the sensation in your right hand.
>
> In the second part, you will see landscape and art slides. In this part we would like you to pay attention only to these slides, so you will be able to answer questions about them afterwards. Try to ignore everything else and pay close attention to the slides. It is very important that you follow the instructions, so pay close attention to the sensations in your right hand in the first part and try to ignore them and pay attention to the slides in the second part.

Timing of procedures. Tape-recorded instructions told the subject when to shift his hand from the warm to the cold water tank and also told him when to make the distress ratings. The subject made 12 judgments of distress during the 5 min. and 15 sec that his hand was immersed in the cold water; the distress scale was the same as that used in Experiments 1 and 2.

The immersion in the cold water was divided into two equal periods of 2 min. and 35 sec each, separated by a 5-sec interval in which the instructions appropriate for the last 2-min. and 35-sec period were repeated. Because it was necessary to repeat the instructions in the conditions in which subjects switched the focus of their attention, the instructions were also repeated in the attention–attention and distraction–distraction conditions. Six distress judgments were made in each 2-min. and 35-sec period. The first was requested 15 sec after the start of each period (15 sec after the instructions to immerse the hand in the water or 15 sec after completion of the between-periods instructions). The second judgment followed 15 sec later. A 30-sec interval was used between the remaining four judgments. To further en-

sure that subjects followed the appropriate procedure, two brief reminders were given during each period, one 45 sec after its start and the second a minute later.

Two different sets of 24 slides were used during each of the distraction periods. The slides were exposed for 5 sec each, and the between-slides interval equaled the time taken for the slide to change. The screen was darkened during the first of the three repetitions of the instructions and for 5 sec during each of the six ratings. The subject was told to remove his hand from the cold water and make four additional distress judgments at 30-sec intervals at the end of the second period.

Postexperimental questionnaires. After the 16 judgment trials, the thermistor was removed, and the subject completed two questionnaires. The first was the sensations and features checklist used in Experiment 2. The second questionnaire included modified versions of the direct questions asking for estimates of the deployment of attention and the questions about tiredness and tenseness. The attention questions had the subject estimate the percentage of time he attended to his hand, his body, the slides, and other features of the setting. An 11-point scale was used for each of the four foci of attention (in 10% intervals from 0% to 100%). The subject was told that his four estimates had to sum to 100%. The estimates were made twice, once for each of the two periods of the cold pressor.

Results

The data for the four conditions were analyzed as a 2 × 2 factorial design with a third repeated measure factor. The first factor was the attentional set (attention vs. distraction) during the first period of the experiment, the second factor was the attentional set (attention vs. distraction) during the second period, and the repeated measure factor was judgment trials.

As can be seen in Figure 5, distress showed a sharp initial increase for the first minute of immersion, peaked at approximately 1½ min into the procedure, and then declined, though differentially, in all groups. Figure 5 also shows that the distress levels declined considerably more in the attention–attention and attention–distraction conditions than in the distraction–distraction and distraction–attention

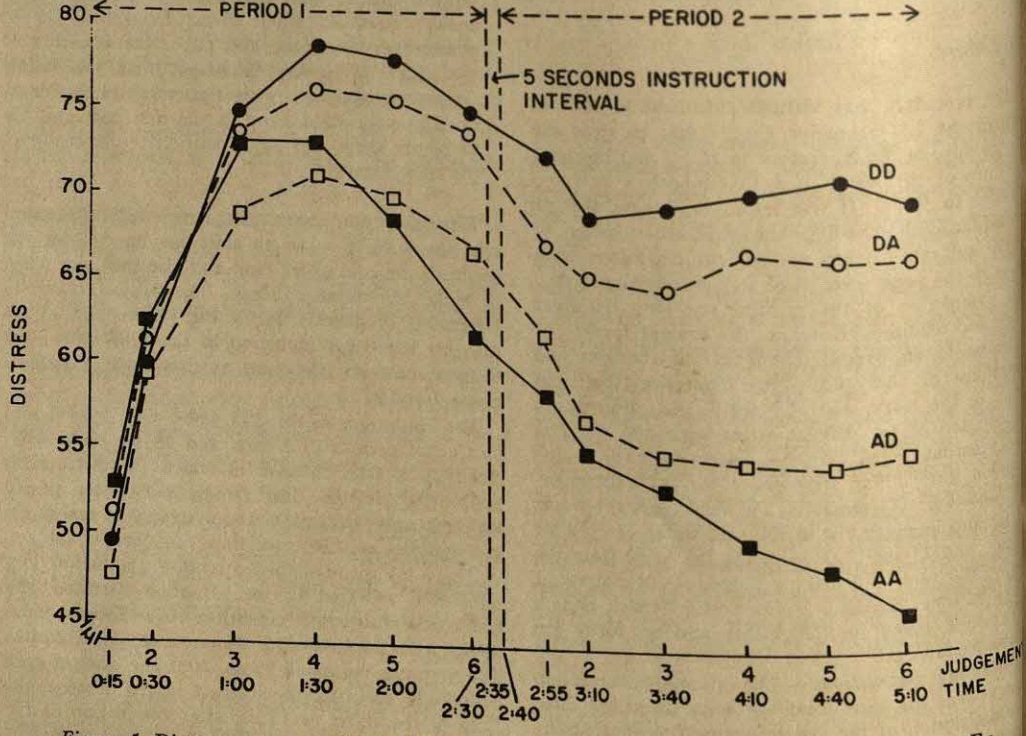

Figure 5. Distress ratings during cold pressor immersion for the four experimental groups in Experiment 3. (DD = distraction–distraction; DA = distraction–attention; AA = attention–attention; and AD = attention–distraction. $n = 16$ in each experimental group.)

conditions. The difference in rate of decline in reported distress resulted in a significant main effect, with the two groups paying attention to the hand in the first period reporting an average level of distress ($M = 59.04$) substantially lower than the average level of distress reported for the two groups that were distracted by slides during the first immersion period ($M = 68.18$), $F(1, 60) = 4.61$, $p < .05$. More important, however, there was an interaction between trials and the attentional set adopted during the first 2-min. and 35-sec period, $F(11, 660) = 5.15$, $p < .001$. The level of distress reported during the second period of cold pressor was substantially lower for the two groups attending to the hand during the first period than was the level of distress for the two groups watching slides during the first period. There were no significant effects as a function of attention or distraction during the second period of the cold pressor.

A pair of subsidiary analyses were conducted, one on the six ratings before the change in instructions from attention to distraction and another on the six ratings made after the change. The analysis of the first period showed an interaction between attentional set and trials, $F(5, 300) = 2.87$, $p < .05$, because the groups, although virtually identical for judgments 1–3, began to separate by the fourth judgment. The peak for the two early distraction groups ($M = 77.0$) was only slightly greater, however, than the peak for the two early attention groups ($M = 71.8$).

In the second set of six judgments, the drop in distress was significantly greater for the groups that were instructed to pay attention to the hand during the first period (the attention–attention and attention–distraction groups) than for the groups that were instructed to watch slides during the first period (the distraction–distraction and distraction–attention conditions), interaction $F(5, 300) = 2.47$, $p < .05$. The difference between the two pairs was sufficiently great to produce a significant main effect as well, $F(1, 60) = 8.46$, $p < .01$. The analyses support the pattern visible in Figure 5 and suggest that early attention to the hand began to affect distress reports $1\frac{1}{2}$ min. after immersion in the cold water and that these effects lasted and became still stronger in the second period of exposure. (Once again, trial effects were highly significant.)

Finger Temperature

Finger temperature dropped during the early part of immersion and rose during the postimmersion period for all conditions, but there were no treatment effects.

Postexperimental Questionnaire Reactions

Focus of attention. Subjects instructed to attend to their hand indicated that they spent a substantially higher proportion of their time monitoring their hand than did subjects not so instructed, in both the first (M attend = 76.5%, M distract = 50.3%), $F(1, 59) = 50.75$, $p < .001$, and the second period (M attend = 79.6%, M distract = 42.9%), $F(1, 59) = 76.05$, $p < .001$, of cold pressor. There were no significant differences for attention to body reactions or to other events in the setting.

The sensation and features checklist showed that *more* attention was paid to the hand (sum of eight items) during the first ($M = 73.7$) than during the second ($M = 58.7$) period of the cold pressor, $F(1, 59) = 17.12$, $p < .001$, whereas the sum of the 11 body sensation items showed less awareness of body responses in the first ($M = 51.7$) than in the second ($M = 66.2$) cold pressor period, $F(1, 59) = 21.97$, $p < .001$. These shifts in awareness from hand sensations in the first half of the cold pressor to body sensations in the second half held for all groups.

Feeling of fatigue. The same three-part question used in Experiment 2, "Toward the end of the time your hand was in the water, did you feel (a) tired, (b) tense and jumpy, (c) detached and daydreamy?" showed a significant effect for the tiredness rating (made on a 21-point scale); subjects who were instructed to attend to their hand in the first half of the cold pressor exposure reported being less tired ($M = 4.30$) than did subjects who were distracted by slides during the early phase ($M = 6.14$), $F(1, 58) = 4.77$, $p < .05$. There were no other significant effects.

Discussion

The results of Experiment 3 confirm and extend those of Experiment 2. First, attention to the site of cold pressor impact produced substantial reductions in reported distress. Second, it was clear that attention during the first portion of exposure was critical for later distress reduction; this finding held for reported distress and for reported fatigue on the postexperimental questionnaire. The introduction of the distractor slides facilitated the deliberate direction of attention and the ease with which subjects could report on its deployment, making clear that subjects gave a higher proportion of attention to the impact site during this early period. And the attentional effects seem to have begun very early, taking hold by the end of the fourth distress judgment or about 1½ min. into the cold pressor test.

Third, there were no signs of decline in reported distress or reported fatigue for subjects who monitored their hand during the second half of exposure; the reports of these subjects did not differ from those of subjects who were continually distracted with slides. It seems that attention during the latter part of exposure is relatively ineffective for distress reduction. While there are many reasons why this may be so, the present data and past observations point to one conclusion in particular. First, it is clear that distress is already at relatively high levels when attention is first deployed to the hand in the distraction–attention group. Second, it is clear that the experience of the cold pressor changes over time; the sensation checklist showed declining awareness of hand sensations and growing awareness of body sensations from the first to the second half of cold pressor immersion. Wolf and Hardy (1943) have detailed the many complex changes in the experience of cold pressor from the coldness and bright, pricking, pain sensations early in exposure to the deeper aching and numbness experienced later on, changes which have been attributed to activity in different fiber systems (Mountcastle, 1968). The earlier experiences are far more localized and informational in nature than the diffuse, unchanging aching sensations that begin to dominate the later pain experience. These latter sensations seem to be of the type that are more easily summated with other sources of input than are the clear, discrete, and localized sensations of early pain experience (Melzack, 1973). In conclusion, it would appear that subjects attending to the impact site in the latter half of exposure would have relatively less information available for the construction of a schema of the stimulus input and relatively more information (diffuse aching) for the formation of a generalized state of arousal and distress. The pattern of findings tends to confirm the hypothesis that monitoring during the onset of stimulation, when features are rich and informative and diffuse, aching distress is relatively low, is optimal for the formation of a stimulus schema and the habituation (or cessation of recruitment) of distress emotion (Sokolov, 1963).

General Discussion

All three of the experiments show that monitoring the impact of noxious stimulation can substantially reduce the emotional distress experience component of the experience on stimulus impact. The studies suggest that the mechanism underlying this effect is the formation of a schema of the objective, or informational, features of the stimulus, which captures new stimulus inputs and reduces the degree to which these new inputs can stimulate distress reactions. This habituation process is empirically similar to that reported in habituation studies in animals (Groves & Thompson, 1970), though the data from the present study point to a mechanism similar to that suggested by Sokolov (1963). It should be understood that the findings do not rule out alternative modes of distress reduction. Analgesic sets, under hypnotic (Hilgard, 1969, 1971) or nonhypnotic conditions (Barber & Hahn, 1962; Melzack, Weisz, & Sprague, 1963; Spanos, Horton, & Chaves, 1975), may also reduce distress to noxious inputs, but the empirical findings in these areas (immediate distress reduction, successful reduction for relatively short periods of time) suggest a different mechanism, namely, the blockage of sensations and distress from conscious awareness, rather than the habituation of distress

per se (Hilgard, 1973; Hilgard, Morgan, & Macdonald, 1975). And it should also be clear that monitoring stimulus inputs does not necessarily lead to distress reduction. If the subject is threatened and regards the stimulus sensations as warnings of further harm and danger, monitoring may enhance emotional distress rather than facilitate emotional habituation. Monitoring may be essential for the occurrence of habituation, but it is not sufficient.

Our interpretation of the cold pressor effects assumes, therefore, two quite different ways of coding or schematizing noxious stimulus inputs—an objective informational coding in which cues are coded for their concrete, immediate meaning and an emotional memory schematization in which cues are coded for their anticipatory, threat value (Engel, 1959; Leventhal, in press; Leventhal & Everhart, in press). The relative strength of these two types of coding will obviously vary as a function of set and subject disposition. The theoretical interpretation is the same as that offered several years ago for the "new look" studies of perception (Bruner, 1957) and in more recent theorizing respecting the role of categorization in awareness (Broadbent, 1977).

While the approach is not novel, it does allow the synthesis of a wide range of data. For example, Morgan and Pollock (1977) studied world-class runners and found that elite runners carefully monitor leg and muscular sensations while performing. Outstanding, but nonelite runners distract from these sensations; they regard them as threat cues or signs of an anticipated wall or limit to their endurance. Thus, monitoring per se is not the critical factor in the runner's control of distress; it is the schematization of the cues that is central. Similarly, cases of phantom pain appear to involve a pain schema of body parts and a vivid central neural representation of the somesthetic and distress reactions associated with preoperative injuries to amputated body parts (Melzack, 1971; Morgenstern, 1970; Simmel, 1962). Case examples illustrate that these painful experiences may vanish if the patient is exposed, by means of epinephrine injection to nerve roots, to a rich panoply of concrete sensations from the missing limb without pain inputs; monitoring the fresh, nonpainful set of stimulus features allows the reassertion of the neutral, nonpain schema of the missing body part.

It also seems that under some conditions, emotional schemata (pain memories) are more available than so-called objective codes. Indeed, the availability of these schemata in real-life situations is very likely responsible for the differences in experimental findings between laboratory and clinical studies of pain (Beecher, 1959). We have been impressed with the reliability with which one can find distress reduction by using monitoring strategies in hospital settings. The patient is in a threatening situation, pain and emotional schematization are highly likely, and distress reduction is readily achieved by combinations of monitoring strategies (sensation information) and reassurance that the procedures will help (Johnson et al., 1975; Johnson & Leventhal, 1974; Johnson et al., 1973; Johnson et al., Note 1; Fuller, Endress, & Johnson, Note 2; Wilson, Note 3).

The field studies also make clear that coping or control is an important factor in the distress-reduction process. The availability of a coping reaction may not only substitute instrumental responding for emotional responding but will also help sustain attention to the objective features of repeated, noxious stimulus inputs, facilitate placing benign interpretations on these inputs, and permit habituation (see Johnson & Leventhal, 1974; Johnson et al., Note 1). For example, a postsurgical cardiac by-pass patient must engage in stretching and breathing exercises that will generate intense sensations and distress from the chest. Knowing what the sensations will be, carefully monitoring them as he or she breathes, and interpreting them as signs of healing and return to normal function will likely encourage the patient's objective schematization of the cues and the habituation of distress reactions. By contrast, an unprepared patient who does not expect the signs and has no way of interpreting them as benign might inhibit coping reactions in order to minimize and distract him- or herself from pain and distress and fears of potential injury.

A complete model of the stress control process will involve, therefore, a series of steps going from the representation of stimulus features to their coding in objective or emotional memory schemata, the execution of coping reactions guided by these cues, and the interpretation or evaluation of feedback from the coping behaviors (Lazarus, 1966). The three experiments reported here addressed only part of the problem. It is also clear that we have merely touched on the process of distress habituation. Habituation may be a passive dropping out of responding (e.g., Groves & Thompson, 1970) or a product of one or more active, inhibitory processes related to gating of noxious stimulus impulses by informational factors (Melzack & Wall, 1965, 1970) or by inhibition generated by endorphins in the medial forebrain system (Snyder, 1977). Interesting questions remain respecting the mechanisms underlying the behavioral effects reported here, and these mechanisms may suggest new psychological manipulations for pain control.

Effects of Pitch and Speech Rate on Personal Attributions

William Apple
Columbia University

Lynn A. Streeter
Bell Laboratories
Murray Hill, New Jersey

Robert M. Krauss
Columbia University

In three experiments, subjects listened to recordings of male speakers answering two interview questions and rated the speakers on a variety of scales. The recordings had been altered so that the pitch of the speakers' voices was raised or lowered by 20% or left at its normal level, and speech rate was expanded or compressed by 30% or left at its normal rate. The results provided clear evidence that listeners use these acoustic properties in making personal attributions to speakers. Speakers with high-pitched voices were judged less truthful, less emphatic, less "potent" (smaller, thinner, faster), and more nervous. Slow-talking speakers were judged less truthful, less fluent, and less persuasive and were seen as more "passive" (slower, colder, passive, weaker) but more "potent." However, the effects of the acoustic manipulations on personal attributions also depended on the particular question that elicited the response.

Human speech provides a listener with at least two sources of information: a *verbal* channel, encoding the message's linguistic content, and a *vocal* channel, conveying paralinguistic information by variations in pitch, speech rate, loudness, and the like.

One important type of information communicated via the vocal channel concerns a speaker's affective state. The vocal characteristics associated with the expression of emotion are beginning to be understood (see, for example, Fairbanks, 1940; Hecker, Stevens, von Bismarck, & Williams, 1968; Williams & Stevens, 1972). It is now reasonably well established that stressful situations raise the voice's fundamental frequency (the number of glottal pulses per second) and that "active" emotions such as anger and fear tend to be reflected in increased mean pitch and pitch variance, whereas "low energy" states such as sorrow and indifference are associated with a lower mean pitch and a slower speech rate.

Given that emotional states do differ reliably in their paralinguistic expression, to what extent do listeners use these vocal cues in judging the immediate affective state or more enduring personality traits of a speaker? An early investigation of the noncontent aspects of speech by Allport and Cantril (1934) demonstrated that listeners could judge, at better than chance levels, a speaker's age and at least some personality characteristics from voice alone: In four of six experiments, speakers' scores on a test of ascendance–submission (Allport's A–S reaction study) were judged with significant accuracy. However, reviewing much of the voice-attribution work, Kramer (1963) concluded that more common than accuracy in such judgment studies was the finding of "vocal stereotypes." That is, certain voices were reliably, though sometimes incorrectly, judged as belonging to certain personality types.

Unfortunately, as Kramer noted, the description of the vocal parameters that under-

We wish to thank John Lin and Nina Macdonald for their valuable assistance. We are also grateful to Myron Wish, Nancy Morency, and four anonymous reviewers for their helpful comments.

lie such stereotypes leaves much to be desired. While not all the earlier research on voice attributions can be faulted on these grounds, studies attempting to specify critical stimulus dimensions often have neglected or confounded important paralinguistic cues. For example, in reporting two recent field experiments, Miller, Maruyama, Beaber, and Valone (1976) concluded that the persuasiveness of a communication can be directly related to the rate at which it is delivered. More rapid speech was found to be more persuasive, presumably because a fast talker is viewed as more credible. Although Miller et al. have ruled out certain alternative explanations (such as the effect of having limited opportunity to counterargue against a rapid presentation), the stimulus materials used in their experiments warrant closer examination. In both experiments the persuasive messages were recorded by the same speaker at either a slow or a fast speech rate. This was accomplished "by simply instructing the speaker to practice delivering the same speech as rapidly and slowly as possible while controlling his level of enthusiasm and involvement" (Miller et al, 1976, p. 618). The stimulus recordings in the two conditions do, of course, differ in speech rate, but it is quite likely that they differ in other respects as well. In natural speech, such vocal parameters as amplitude, pitch, and rate tend to covary. For example, rapid speech is likely to be louder and higher pitched than normal speech (Black, 1961). Consequently, it is quite possible that subjects in the Miller et al. study were responding to pitch and/or loudness cues as well as to rate.

Because it is so difficult to assess, in a controlled way, the contribution of various vocal parameters to the attribution process using natural speech, a number of workers have attempted to deal with the problem by using nonspeech stimuli. For example, Scherer (1974) presented listeners with simple tone sequences generated on a Moog synthesizer, in which a minimal set of acoustic cues (pitch level and variation, amplitude level and variation, and tempo) were varied factorially; listeners rated the emotional quality of these tone sequences on a set of semantic differential scales. Scherer found that judgments were most influenced by tempo and pitch variations: Fast tempo led to attributions of highly active and potent emotions (e.g., interest, anger, and happiness) and slow tempo to attributions of sadness, disgust, and boredom; extreme pitch variation with rising contours produced ratings of highly pleasant, active, and potent emotions (happiness, surprise, interest). Other parameters influenced the perception of specific emotional qualities. While Scherer's method effectively deals with the confounding of vocal qualities in natural speech and suggests the effect that independently varied acoustic cues can exert, in view of the artificial nature of the stimuli used, it is not clear how directly the results can be generalized to the processing of speech.

Other investigators, using natural speech, have achieved a degree of control over stimulus materials by means of editing techniques. For example, investigators have added or removed such speech disfluencies as filled pauses and repetitions from stimulus audiotapes and asked listeners to judge speakers' credibility and other personal attributes (Lay & Burron, 1968; Miller & Hewgill, 1964). Typically, highly hesitant or disfluent speakers are assigned relatively undesirable personality traits, and their communications are judged to be low in credibility.

While the methods thus far described have all afforded some degree of stimulus control, recent developments in speech synthesis technology permit investigators to vary independently one or more parameters of natural speech. This approach has been exploited by Brown and his colleagues (Brown, Strong, & Rencher, 1973, 1974; Smith, Brown, Strong, & Rencher, 1975), who have manipulated speech rate, mean fundamental frequency, and fundamental frequency variance, using a computer-based analysis–synthesis system. Two major personality dimensions (termed "competence" and "benevolence") have emerged from factor analyses of judgments of such manipulated speech. Generally speaking, higher pitch seems to result in a speaker being judged less competent and less benevolent (Brown et al., 1974), whereas faster speech rates produce judgments of higher

competence but yielded an inverted-U relationship on the benevolence dimension (Smith et al., 1975).

The studies of Brown and his associates make an important contribution to our understanding of the significance that listeners ascribe to vocal qualities. Nevertheless, they are not free of methodological problems. They typically have relied on a small number of stimulus voices, all of whose acoustic permutations are presented to the same raters. For example, the Brown et al. (1974) study used only two adult male speakers uttering the same sentence ("We were away a year ago"), which was then manipulated to fill the 27 cells of a $3 \times 3 \times 3$ factorial design. It is not clear that judgments based on hearing 54 repetitions of the same content bear much similarity to the kinds of everyday personality ascriptions listeners make under more natural conditions. Additionally, the particular parametric values used in these studies are problematic. Brown et al. (1974) reported that in the high-pitch condition, the original fundamental frequency was multiplied by a factor of 1.8. Although they did not report average fundamental frequency values for their two speakers, assuming that they fell into the normal range for males, Brown et al.'s high-pitch manipulation would have raised a male voice into the female range. Similar criticisms apply to their choice of speech-rate scale factors.

The present article reports an exploratory series of experiments designed to demonstrate the effects of two acoustic parameters—average fundamental frequency and speech rate—on judgments of several state and trait variables. It was hoped that by using a large number of speakers and naturally produced utterances, together with more conservative values for acoustic alteration, and by independently manipulating the two parameters factorially, we could overcome the methodological problems noted above.

Experiment 1

Experiment 1 derives from a finding reported by Streeter, Krauss, Geller, Olson, and Apple (1977), who demonstrated that the mean fundamental frequency of speakers' voices increased when they lied, relative to a truth-telling baseline, and that this effect was stronger when the speaker had been motivated to lie effectively. In addition, Streeter et al. found that although judges' ratings of truthfulness were essentially uncorrelated with pitch level, there *was* a significant negative correlation between judged truthfulness and average pitch for listeners who heard the speech after it had been passed through a content filter—a device that destroys intelligibility without affecting vocal features of the utterances. Apparently, the natural pitch increments during lying (on the average about 3 Hz) were too small to affect the judgments of listeners who had content available but were taken into account by listeners who could not understand the responses' verbal content. However, since pitch increments and speech rate decrements were correlated in their data, Streeter et al. could not rule out the possibility that listeners were attending to rate differences rather than pitch differences between true and false utterances. From the finding of Miller et al. (1976), one would expect slower speech to result in lower perceived speaker credibility. In Experiment 1 we assessed the effects of these two variables on truthfulness judgments.

Method

Stimulus materials. Forty male Columbia College undergraduates, all native speakers of English, answered questions for use as stimulus materials. They were individually recorded in a sound-isolated booth on high-quality audio equipment, and they received course credit for their participation. Each speaker answered six standard questions dealing with his opinion on a range of topics. The questions were administered in a fixed order, and speakers were instructed to answer all questions honestly and frankly. They were told to give brief answers, but to give more than a yes-or-no response. All speakers were debriefed concerning how their interviews might be used and signed informed-consent releases permitting the later use of the recordings.

Two of the six interview questions were selected for use in the experiment. One asked the subject's opinion of college admissions quotas designed to favor minority groups (Question 3); the other asked the subject what he would do if he suddenly won or inherited a large sum of money (Question 6). These two questions were chosen because both elicited a diversity of responses and because the two differed

on a dimension of personal salience for the respondents. (The question of quotas is a matter of genuine concern and frequent discussion among Columbia undergraduates.) Twenty-seven speakers, who gave responses that were not excessively long and represented the spectrum of opinions on the two questions, were selected.

Each of the 27 speakers was then randomly assigned to one of nine cells of a 3 (rate: slow, unmanipulated, fast) × 3 (pitch: low, unmanipulated, high) completely crossed factorial design, with three speakers in each cell. All speech material was digitized and analyzed by the linear predictive coding (LPC) method of Atal and Hanauer (1971). (The LPC analysis calculates 14 parameters every 10 msec. Twelve of these parameters represent pseudoarea functions of the vocal tract; the other two are values for amplitude and fundamental frequency. The advantage of LPC analysis is that such variables as rate, pitch, and amplitude can be manipulated without changing other voice parameters. In addition, since the parameters are derived from the original speech, the quality of the resulting synthesis is high.) The two responses of each speaker were manipulated on a DDP-224 computer using an interactive program (Nakatani, Note 1) that displays the parameters as functions of time and allows the user to manipulate any or all of the 14 parameters as well as to linearly expand or compress the time base. The altered utterances can then be synthesized and recorded on audiotape.

The scale factors chosen for the low- and high-pitch manipulations were 80% and 120%, respectively, of the speaker's unmanipulated fundamental frequency. The values chosen for the slow and fast speech rate manipulations were 70% compression and 130% expansion, respectively, of the utterance's time base, resulting in speech rates that were 77% and 143% of the unmanipulated rates.[1] These scale values were chosen because the resulting speech still sounded natural and the acoustic properties remained more or less within the normal range of values. (See Hanley, 1951; Mysak, 1959; Peterson & Barney, 1952; and Terango, 1966, for data on pitch and Goldman Eisler, 1968, for normative speech rate data.) The mean premanipulation fundamental frequency and speech rate for our speakers were 109.79 Hz ($SD = 14.82$) and 3.27 syllables/sec ($SD = .66$). Following manipulation, all utterances were resynthesized to produce a stimulus audiotape of the answers to the quota question (in one random order) and a tape of the answers to the money question (in a different order). The tapes were formatted to allow 15 sec of silence between each response.

Procedure. Twenty undergraduates, 14 males and 6 females, were paid for their participation.[2] Raters were run in groups of three to seven. They were told that the purpose of the study was to determine how well people can tell, from the sound of the speaker's voice, whether someone is lying or telling the truth. They were informed that approximately half the speakers had been instructed to tell the truth, whereas the remaining half had been told to lie—that is, to give answers that did not correspond to their actual beliefs or feelings.

The two stimulus tapes were played over high-quality audio equipment with the order of tape presentation counterbalanced. A 500-Hz warning tone preceded and followed each answer by 1 sec. Raters were given 15 sec in which to rate the truthfulness of the answer on a 7-point scale ranging from "not at all truthful" (1) to "entirely truthful" (7).

Because of variations in the quality of the recordings, raters were also told that recordings had been made using a variety of equipment in several different environments.[3] The experimental session lasted about an hour, and there was a 5-min. rest period between tapes. Participants in the three rating studies were sent a report describing the purpose and detailing some of the findings of the study several weeks after its conclusion.

Results

Some of the premanipulation characteristics of the stimulus materials are summarized in Table 1. Note that the more involving topic, college admissions quotas, resulted in significantly longer, slower, and higher pitched responses. Since the quota topic always preceded the money topic in the original order, we cannot rule out the possibility that these differences are due to serial position effects.

---

[1] The rate manipulation algorithm linearly expanded or compressed consonant and vowel information alike. In natural speech, rate variation tends to be reflected more in changes of vowel duration than in consonant duration. However, the rate manipulation used resulted in reasonably natural-sounding speech.

It may not be immediately apparent why 70% compression of an utterance's time base results in a speech rate that is 143% of the original. Consider a response consisting of n syllables spoken over s seconds of time; that utterance's rate would be n/s syllables/sec. Seventy-percent compression changes the rate to $n/(.7s)$, or $1.43\ n/s$—a faster speech rate that is 143% of the original. Likewise, a 130% expansion of an utterance's time base results in a slower speech rate that is 77% of the original rate.

[2] One additional rater was run, but his data were discarded after he expressed some suspicion regarding possible splicing of the tapes. No other raters voiced any suspicion that the stimuli had been altered.

[3] There is some quality variation across speakers in the LPC synthesis; in particular, speakers who tend to mumble and have a high degree of nasalization seem to suffer the greatest quality degradation.

Table 1
Premanipulation Characteristics of Stimulus Tapes

	Quota tape		Money tape		
	M	*SD*	*M*	*SD*	*t*
Response length (syllables)	111.1	40.7	84.6	42.7	3.89**
Response time (sec)	36.8	13.8	25.6	13.2	4.68**
Speech rate (syllables/sec)	3.0	.50	3.4	.74	2.12*
Fundamental frequency (Hz)	112.2	14.9	107.4	14.6	5.60***

Note. $N = 27$ segments per tape.
* $p < .05$, two-tailed. ** $p < .01$, two-tailed. *** $p < .001$, two-tailed.

However, it seems more plausible to regard these differences as reflections of differences in our subjects' personal involvement with the two questions and/or the cognitive complexity of the answers they called for (see Goldman Eisler, 1968, and Williams & Stevens, 1969).

To check the adequacy of the random assignment, premanipulation speech rate (syllables/sec) and average pitch were subjected to analyses of variance (3 rate levels × 3 pitch levels × 2 questions) with speakers nested within the rate and pitch factors. In addition to the between-questions differences already noted, the analysis of the premanipulation pitch failed to reveal other significant effects. However, there was a marginally significant difference in premanipulation speech rate across the three assigned rate conditions, $F(2, 18) = 3.00$, $p < .08$, primarily because of some slower speakers' random assignment to the slow rate condition. Therefore, prior to all further analyses, we adjusted the raw data for covariation on speakers' premanipulation speech rate and fundamental frequency: The appropriate beta weights were derived from linear regression of the data collapsed across raters. This adjustment has the virtue of controlling for spurious rate and question effects in the analyses of variance.[4] Having thus transformed each dependent variable, we computed min-F ratios (and their approximate degrees of freedom) for the analyses of variance. The F'' statistic we report (Winer, 1971, pp. 375–378) treats both speakers and raters as random effects, permitting simultaneous generalization over both groups.[5]

A 3 (pitch levels) × 3 (rate levels) × 2 (questions) analysis of variance was performed on the mean truthfulness ratings with repeated measures on the last factor. Premanipulation speech rate and premanipulation fundamental frequency were used as covariates, and all means reported below have been adjusted for these covariates. A significant main effect was found for the pitch manipulation, $F''(3, 34) = 3.37$, $p < .05$, and a marginally significant effect for rate, $F''(3, 51) = 2.26$, $p < .10$. The mean truthfulness ratings for the three pitch conditions (going from low to high pitch) were 4.62, 4.40, and 4.09, respectively, indicating that lower pitch enhanced credibility. The corresponding means for the rate manipulation were, going from slow to fast rate, 4.10, 4.63, and 4.37; the unmanipulated rate was judged most credible and the slow rate least credible.

No significant effect was found for the

[4] To ensure that our subjects' ratings were not affected by variations in acoustic quality across our nine experimental conditions, we had six undergraduates rate the 54 recorded segments for intelligibility and correlated these ratings with our subjects' ratings of truthfulness. The two sets of ratings were not significantly correlated ($r = .15$). Similarly, to ensure that response content was well distributed across conditions, we had 12 undergraduates rate from a transcript how pro- or antiquota (for the quota question) or generous or selfish (for the money question) each response was. Their ratings were then subjected to a 3 (pitch levels) × 3 (rate levels) analysis of variance. For neither question were significant main effects or interactions found.

[5] In cases where the min-F value (F'') is marginal, we will also report the conventional F ratios for raters (considering speakers as a fixed effect) and speakers (considering raters as a fixed effect). These values represent less conservative tests.

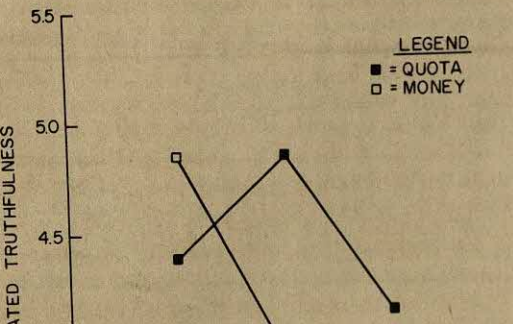

Figure 1. Average rated truthfulness plotted as a function of pitch condition (low, normal, high) for each of the two question topics.

Pitch × Rate interaction. However, there was a nearly significant Pitch × Question effect, $F''(2, 32) = 3.02$, $p < .10$; raters' $F(2, 38) = 10.25$, $p < .001$; speakers' $F(2, 18) = 3.84$, $p < .05$. For the quota question, truthfulness ratings and pitch were curvilinearly related; for the money question, low-pitched speakers were judged as most truthful. The two sets of means are shown in Figure 1.[6]

Discussion

The results demonstrate that the acoustic manipulations performed on the speech stimuli affected judgments of truthfulness. Consistent with the findings of Streeter et al. (1977), judges rated high-pitched voices as less truthful than lower pitched voices. Perhaps listeners perceived high pitch to be an indication of stress and attributed such stress to attempted deception. The pitch manipulations used, although not extreme enough to place voices outside the normal male pitch range, were evidently large enough to produce attributions of lying from naive listeners. It will be recalled that the smaller, naturally occurring pitch increments accompanying deception in the Streeter et al. experiment did not evoke such attributions, except in the filtered listening condition, in which verbal content was unintelligible.

While the rate effect was only marginally significant, it appears that the effect of rate on truthfulness judgments is not linear; rather, the pattern is an inverted-U function, with slower speech perceived as least credible. These results are consistent with the findings of Miller et al. (1976), who demonstrated that a faster speaker was perceived as more intelligent, knowledgeable, and objective than a slower speaker. Since Miller et al. used only two levels of speech rate, it is, of course, not possible to establish the effect of intermediate rates on credibility judgments in their study. It is relevant, however, that Brown and coworkers have reported a similar inverted-U relationship between manipulated speech rate and their "benevolence" dimension, on which the adjective pair sincere–insincere loads significantly (see Smith, Brown, Strong & Rencher, 1975). To the extent that ratings of sincerity correspond to this study's truthfulness measure, the two results are consistent.

The most plausible explanation of the Question × Pitch interaction (Figure 1) is that listeners took question content into consideration in making their truthfulness judgments. When listening to a potentially "loaded" topic (quota question), raters were willing to call both low- and normal-pitched voices more truthful than high-pitched voices. For the less involving question (money), raters were willing to call only low voices more truthful. This interaction argues for a pitch threshold, above which deception is signaled to raters. Such a threshold would interact with response content, so that for an emotionally involving topic, it would be set higher than for a less involving topic. With an emotionally involving topic, some of the vocally reflected stress can be attributed to the topic; given a non-involving topic, the high-pitch responses are likely to be attributed to attempted deception. However, since only two questions were used, further research is needed to test this content-attribution hypothesis.

The truthfulness ratings reflect judgmen

[6] The corresponding analysis performed on the intelligibility ratings revealed a significant effect only for the rate manipulation, with fastest speech suffering greatest loss in intelligibility.

processes that give rise to attributions of a speaker's transient state. If listeners had not been told that certain speakers were lying, differences in the acoustically manipulated variables might have been seen as enduring vocal properties reflecting stable personal predispositions. Such properties have been referred to by the linguist Trager (1958) as the "voice set" and involve "the physiological and physical peculiarities resulting in the patterned identification of individuals as . . . persons of a certain sex, age, state of health, body build, rhythm state" (p. 4). The voice set, therefore, acts as a relatively permanent background against which transient vocal changes are superimposed. In the absence of situational factors (e.g., the possibility that the speaker was lying) that could explain the voice qualities produced by our acoustic manipulations, listeners would be likely to ascribe such qualities to the voice set. How such variables affect person perception and contribute to vocal stereotypes was explored in Experiment 2.

Experiment 2

Method

Stimulus materials. The quota and money tapes from Experiment 1 were used.

Procedure. Eleven college students, nine males and two females, were paid for their participation as raters. The procedure was essentially the same as that used in Experiment 1, with the following differences: Raters were instructed that the study's purpose was to investigate how listeners form impressions of speakers from the things they say as well as from the way they say them. Accordingly, raters were told to focus both on content and delivery when making their judgments.

The speaker of each recorded segment was rated on nine bipolar adjective pairs taken from the semantic differential (Osgood, Suci, & Tannenbaum, 1957); scales were chosen that had high loadings on one of Osgood et al.'s semantic space factors and relatively low loadings on the other two. The scales for the evaluation factor were sour–sweet, awful–nice, and bad–good. Scales for the potency factor were thin–thick, small–large, and weak–strong. Those for the activity factor were slow–fast, cold–hot, and passive–active.

A warning tone followed each recorded segment, signaling judges to begin making the nine ratings on 7-point scales. (The second adjective of each pair was scored as 7.) Instructions stressed that ratings should reflect the listener's impression of the speaker and not agreement or disagreement with the content of the answer. Subjects were told that all speakers had answered the questions truthfully.

Results

Means of the nine scales were computed for each recorded segment, and the intercorrelation matrix was factor analyzed using principal factoring followed by a varimax rotation. A three-factor solution accounted for 84.5% of the total variance and roughly corresponded to the three dimensions of Osgood et al.'s (1957) semantic space. We chose scales loading greater than .60 (in absolute value) as representative of the respective factors. Using that cutoff, Factor 1 consisted of all three activity scales (slow–fast, cold–hot, and passive–active) as well as the strong–weak scale; it accounted for 54.4% of the variance. Factor 2 was a pure evaluation dimension (with only the three evaluative scales loading appreciably: sour–sweet, awful–nice, bad–good); it accounted for 20.2% of the variance. The third factor consisted of two potency scales (thin–thick, small–large) and an activity scale (slow–fast); it accounted for 9.9% of the variance.

Each rater's data were reduced to three factor scores weighting the original scales by the factor loadings; the factor scores were adjusted for covariates (as in Experiment 1) and entered into univariate analyses of variance of the same design as that used in Experiment 1.

For Factor 1, a significant rate effect, $F''(2, 32) = 10.49$, $p < .001$, and a nearly significant Rate × Question interaction, $F''(2, 31) = 3.02$, $p < .10$, were obtained; raters' $F(2, 20) = 9.72$, $p < .01$; speakers' $F(2, 18) = 3.87$, $p < .05$. The configuration of means is shown in Figure 2. In both cases, slow speakers were perceived as less active. No significant main effects of interactions were found for Factor 2. For Factor 3, significant main effects were found for rate, $F''(2,36) = 12.87$, $p < .001$, and pitch, $F''(2, 33) = 7.94$, $p < .01$. In both cases the relationship was monotonic, with increasing pitch and rate resulting in judgments of decreasing potency. No other significant effects were found.

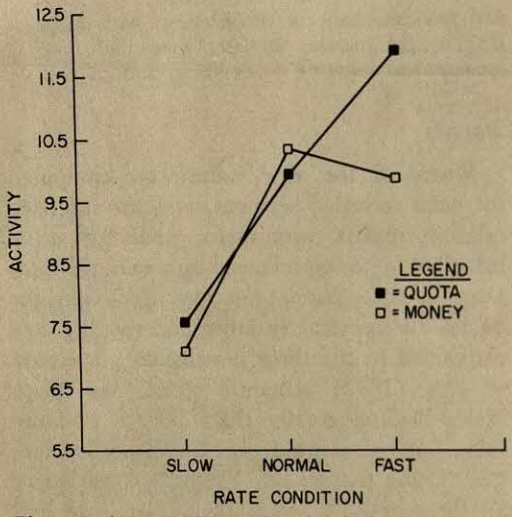

Figure 2. Averages for the activity factor plotted as a function of rate condition (slow, normal, fast) and question topic.

Discussion

These results extend the findings of Experiment 1 to judgments of more stable speaker dispositions. Men speaking in higher pitched voices were perceived as less potent (smaller, thinner, slower) and slow-speaking men were perceived as more passive (slower, colder, more passive, weaker) and more potent.

These findings are to some extent consistent with correlational evidence provided by Scherer, Koivumaki, and Rosenthal (1972). In their experiment, listeners rated taped segments, taken from a recorded play, on semantic differential scales similar to the ones used here, as well as on scales reflecting the segments' acoustic properties (e.g., bass–treble, soft–loud). Unlike the present study, raters judged the emotion portrayed and not their impression of the speaker, and a variety of listening conditions were used to degrade semantic content and prosodic features. Nevertheless, Scherer et al. found a marginally significant relationship between pitch rating (bass–treble) and potency ratings (strong–weak) paralleling the main effect reported above: Lower pitched speech was placed toward the "stronger" pole in the potency dimension of the emotional-meaning space. In contrast to our results, they also found a marginal correlation between articulation rate (slow–fast) and potency ratings: Segments with slower speech were rated as "weaker." Not surprisingly, Scherer et al. also found that segments with faster speech were heavily loaded on the activity dimension.

Our findings are likewise consistent with the results of Brown et al. (1974). Although the methodological differences previously noted preclude direct comparison, Brown found that high fundamental frequency decreased competence ratings—a scale probably related to our potency dimension.

The Rate × Question interaction (Figure 2) again suggests the influence that content exerts on raters' judgments: When speakers talked about quotas, ratings on the passive–active dimension were linear with manipulated rate; for the money question, they were not.

Experiment 3

Experiment 3 returned this work to the area of judgments of the speaker's affective state. Impressions of nervousness, emphaticness, seriousness, fluency, and persuasiveness illustrate how these acoustic variables serve to convey a speaker's self-presentation under conditions in which raters believe that answers are being given honestly. These state ratings (with the exception of persuasiveness) were chosen because Krauss, Geller, and Olson (Note 2) found significant correlations between them and truthfulness ratings in a previous study of deception interactions.

Method

Stimulus materials. The quota and money tapes from Experiment 1 were used.

Procedure. Ten college-student subjects, two males and eight females, were paid to rate all segments on five state variables: fluency, emphaticness, persuasiveness, nervousness, and seriousness. The rating scales spanned 7 points, with 1 indicating that the smallest amount of a variable was judged and 7 indicating that the largest amount was judged. For example, anchors of the nervousness scale were "Not at all nervous" and "Very nervous." Subjects were encouraged to adopt their own criteria for all ratings; no external standards were given. Instructions were virtually identical to those used in Experiment 2. Again, listeners were asked to take into consideration both the content of an answer and the manner in which it was delivered.

Table 2
Min-F Values for the Five State Variables

State variable	Rate (R) effect	Pitch (P) effect	Question (Q) × R	Q × P
Persuasiveness	3.93**	2.94*	3.54**	
Fluency	6.03***		4.07**	2.73*
Emphaticness	6.66***		3.12**	3.33**
Nervousness	6.16***	5.90***		
Seriousness				4.60**

* $p < .10$. ** $p < .05$. *** $p < .01$.

All other procedural details were identical to those of Experiment 2, except that this study was run at Bell Laboratories, using students from a number of colleges who were home on summer vacation.

Results

Segment means were computed for all state measures and analyzed using covariance analyses as described above. Table 2 summarizes the findings. Note that all variables with the exception of seriousness show main effects for the rate manipulation. These effects are all of the inverted-U type with the normal (unmanipulated) speakers judged most fluent, persuasive, and so forth, and slow speakers judged lowest on these scales. (Ratings of nervousness go in the direction opposite to the other three scales.)

Only nervousness yielded a significant main effect for pitch; the pitch manipulation was marginally significant for persuasiveness. Rated nervousness increased with higher pitch, whereas rated persuasiveness decreased.

In addition, ratings of emphaticness and seriousness showed significant Question × Pitch interactions. The shape of these interactions, shown in Figure 3, is quite similar to the corresponding effect on judged truthfulness (Figure 1). For the quota question, only the highest pitched group was "underrated" on emphaticness and seriousness, whereas for the money question, both the normal- and high-pitched groups were "underrated." The fluency measure showed a comparable interaction.

There were Question × Rate interactions for fluency, persuasiveness, and emphaticness. All interactions had a similar shape; for the quota question only the slowest group suffered low ratings, while for the money question both the slow and fast groups received low ratings. The effect for seriousness judgments was marginally significant, but of the same shape.

Discussion

These results again demonstrate the effect acoustic variables have on person perception processes. Decreasing speech rate has a particularly deleterious effect on a speaker's perceived persuasiveness, fluency, and emphaticness. Similarly, increased pitch lowers ratings of persuasiveness and increases greatly the impression of nervousness.

Our findings also suggest that context plays a role in the attribution process, as evidenced by the question interactions. When a speaker

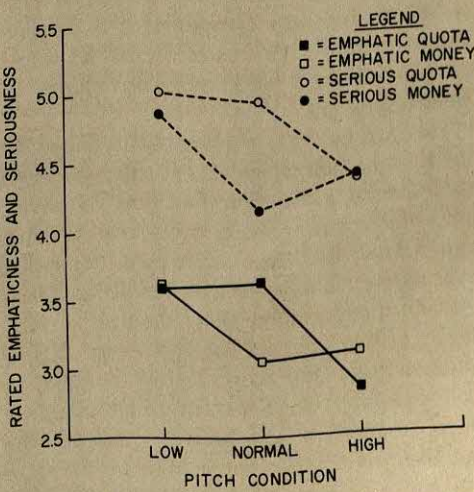

Figure 3. Average emphaticness and seriousness ratings plotted as a function of pitch condition (low, normal, high) and question topic.

answered the quota question, higher pitch levels could be discounted by attributing them to the stressfulness of the topic. Similarly, it may have been inappropriate on the money topic to talk too slowly, (perhaps because of the topic's relative simplicity) or too rapidly (perhaps because rapid speech is perceived as an attempt to be inappropriately serious or persuasive). On the other hand, rapid speech on the quota question might have been attributed to the speaker's conviction regarding his argument.

General Discussion

The three experiments taken as a whole provide clear evidence that acoustic properties of a message have considerable impact on judgments of a variety of state and trait variables. The impressions of high-pitched or slow-talking speakers seem particularly negative. For example, men with high-pitched voices are judged less truthful, less persuasive, weaker, and more nervous. Similarly, slow-talking men are judged to be less truthful, fluent, emphatic, serious, and persuasive, and more passive, although they are also seen as more potent.

By using a large number of speakers and factorially varying speech rate and pitch, we have a reasonable measure of confidence in the validity of our findings. However, since no female voices were used, we cannot generalize these results to women; it is conceivable that these same acoustic variables would produce different effects on perceptions of women speakers.

Message context, presumably mediated by the two question topics, was also demonstrated to influence attribution processes. However, since there was only one question of each type, what follows must remain somewhat speculative. The question interactions suggest an interpretation along the lines of Kelley's (1971) discounting principle. Kelley suggests that the more factors a situation contains—any one of which might plausibly have resulted in an observed outcome—the less likely is any one factor to be perceived as the cause of that outcome. With fewer possible causes present, the cause-to-effect attribution is more compelling. We hoped that our acoustic manipulations would be potent enough to affect speaker state or trait attributions. However, it is evident that listeners may have, at least partially, attributed our acoustic alterations to the question topic. The quota question called for an answer that was both complex and emotionally involving for our college-student speakers and raters. As Table 1 shows, before any manipulations were done, the quota answers were longer and slower (suggesting greater cognitive complexity; see Goldman Eisler, 1968) and higher pitched (suggesting greater stressfulness; see Hecker et al., 1968). Because of this, slower and higher pitched answers might have been perceived as more appropriate for quota responses than for money responses.[7] But even when premanipulation speech rate and pitch were covaried, the question interactions remained, supporting the discounting principle. For example, higher pitch levels seemed to be discounted on ratings of truthfulness, fluency, emphaticness, and seriousness for speakers answering the quota, but not the money, question.

It should be noted that manipulating fundamental frequency by multiplying by a scale factor as we did has the effect of multiplying the *variance* of the fundamental frequency by the square of the scale factor. Thus, high-pitched segments were both high-pitched and high pitch-variance segments, and vice versa. Thus, we cannot rule out the interpretation that the pitch effects observed could be pitch-variance effects. However, this interpretation seems unlikely considering the findings of Brown et al. (1974), who did the appropriate factorial experiment and found that increased mean fundamental frequency lowered judgments of speakers' competence and benevolence, while decreased variance also lowered these ratings. Thus, it seems that average pitch and pitch variance affect judgments on

[7] Subsequently, in connection with another study, we had 12 undergraduates rate a long list of potential interview topics (including the two used in the present study) as to how stressful and how complex they would be for a typical Columbia undergraduate to discuss. Subjects judged the quota question to be significantly more stressful and more complex than the money question.

a wide range of scales in opposite ways. In the present study, in which both pitch and pitch variance were positively correlated, the pitch-correlated variance could only have attenuated the effects of average pitch.

Given that the experimental manipulations used here affected the perception of speakers' personality and state, it remains to be explained why these particular data patterns were observed. Miller et al. (1976), for example, conclude that the effect of speech rate on message persuasiveness is mediated by the effect that variable has on the perception of a speaker's credibility. This, they assert, is a "less rationalistic view" of attitude change than other interpretations (e.g., change mediated by comprehension effects or counterargument disruption—two hypotheses their experiments ruled out).

Certainly such a conclusion would be justified if it were the case that variations in voice quality bore no relation to the actual internal state or predisposition of the speaker. However, there is considerable evidence that stressful situations do produce discernible changes in voice quality (Fairbanks, 1940; Hecker et al., 1968; Williams & Stevens, 1969, 1972), and it seems reasonable to assume that listeners in the present study used such variations appropriately to infer a speaker's state from the quality of his speech. For example, Hecker et al. demonstrated that task-induced stress raised the fundamental frequency of those speakers who did not talk more softly under stress. In our experiment, attributions of increased nervousness to higher-pitched speakers are quite "rationalistic," given the similarity of our pitch manipulations to the effect of real-life stress. Similarly, Streeter et al. (1977) demonstrated that pitch increments accompany deceptive responses; listeners' truthfulness judgments in Experiment 1 appropriately reflect this relationship.

The effects of speech rate can be similarly interpreted in light of Goldman Eisler's (1968) finding that rate and the cognitive complexity of the topic were negatively related. Listeners may have assumed that lying increases speakers' cognitive load, resulting in slower rates. Unpublished speech rate data from the Streeter et al. (1977) study lend plausibility to this argument. A marginally significant interaction ($p < .08$) indicated that subjects did, in fact, speak more slowly when lying than when telling the truth, provided they had been given instructions engaging their motivation to lie effectively. However, speakers not receiving such instructions spoke more rapidly when lying.

Judgments of what is or is not "rationalistic" are probably to a large extent matters of personal preference, but it does seem to us that a listener would be ill-advised to ignore reliable information concerning a speaker's internal state in evaluating the speaker's message, especially when the internal state seems incongruent with the situation or with the message's content.

Furthermore, the significant Question × Manipulation interactions for ratings of state variables suggest some qualifications on the findings of Miller et al. (1976). Fast speakers are not always more persuasive; talking too quickly in response to the money question produced lower persuasiveness ratings than did responses at a normal rate. Apparently, listeners take more into account than meets the ear—at least, more than simply the acoustic data.

Evidence of veridicality for vocally based attributions of enduring personality traits is less firm. We have found no reliable data to indicate that fast talkers actually are more active people or that higher pitched men are weaker than their lower pitched counterparts. Apart from studies of psychiatric patients, much of the work in this area deals with the traits of introversion–extraversion and dominance. Mallory and Miller (1958) found small but significant negative correlations between *judged* pitch and rate and the dominance scale of the Bernreuter Personality Inventory. While these findings support our results on judged potency along the pitch dimension (Experiment 2), it is possible that Mallory and Miller's acoustic judgments are either inaccurate or subject to biasing effects from other sources, since raters judged speakers in a live situation. Furthermore, our results for judged potency on the speech-rate variable appear opposite to Mallory and

Miller's. A more recent study (Ramsay, 1966) found that the speech of subjects classified as extraverts on the Eysenck Personality Inventory had longer unbroken phonation times and shorter silences than those of introverts across a variety of speaking tasks; no data on speech rates were presented.

The acoustic stimulus, of course, contains more information than average pitch and rate. In addition, there is sequential information (provided by intonation contours and duration pattern), loudness, and variability of both pitch and loudness over time. There is also voice quality information (e.g. "breathy" or "raspy" voices) that may not be so readily specified in terms of physical parameters. All of these factors can be expected to enter into the person perception process via stereotypes with larger or smaller kernels of truth.

On none of the measures we examined was the Rate × Pitch interaction statistically significant. The median F interaction was 1.12—close to its expected value under the null hypothesis. This absence of interaction argues for an additive model, in which pitch and rate exert independent effects on listeners' judgments. It remains to be seen whether support for such a model will continue as the role of additional vocal factors is explored.

Corrections to Koretzky, Kohn, and Jeger

In the article "Cross-Situational Consistency Among Problem Adolescents: An Application of the Two-Factor Model" by Martin B. Koretzky, Martin Kohn, and Abraham M. Jeger (*Journal of Personality and Social Psychology,* 1978, Vol. 36, No. 9, pp. 1054–1059), there are errors in two correlations reported in the first paragraph on page 1058. The Factor I and Factor II scores for the Koretzky (1976) study cited there should be reversed. The correct correlation for Factor I is .40, and for Factor II it is .60. Thus, the sentence should read, "Consistency correlations between classroom and residence settings were even stronger in this experiment for Factor II ($r = .60$) and were also respectable for Factor I ($r = .40$)."

Martin B. Koretzky's affiliation was erroneously given as the Veterans Administration Hospital, Bronx, New York. His affiliation at the time of the original research was the State University of New York at Stony Brook.

Smiles Can Be Back Channels

Lawrence J. Brunner
Department of Behavioral Sciences
University of Chicago

The placement of auditor smile beginnings in the stream of dyadic interaction was investigated, using detailed transcriptions of the language, paralanguage, and body motion of the participants in four two-person conversations recorded on videotape. Auditor smile beginnings showed a strong tendency to occur at the same kinds of location as "back channel" responses (such as "yeah," "uh-huh," and head nods). This finding indicates that the smile can function as a type of back channel. It is argued that smiles, like other forms of back channel, make communication more efficient by providing the speaker with feedback on a number of levels simultaneously.

Most quantitative investigations of smiling in adults (see reviews by Berlyne, 1969; Chapman & Foot, 1976; and Goldstein & McGhee, 1972) have treated it as expressive of underlying states such as mirth or pleasurable arousal. Possibly because researchers in social psychology and personality tend to focus their attention more on hypothetical constructs than on the behavior that those constructs are intended to explain (a thesis that Fiske, 1978, argues cogently and in detail), the frequent failure to find significant correlations between ratings of amusement and actions such as smiling and laughing (Chapman, 1976, pp. 156–157) has been attributed (by Berlyne, 1969, and Chapman, 1976, for example) to the greater "sensitivity" of self-report measures.

The present study is deliberately opposite in approach. Without denying that people often smile when they are happy or when something strikes them as funny, it is concerned with smiles as actions rather than expressions of unobservable inner states. It is an attempt to partly specify the "meaning" of smiles—specifically, the smiles of the person who is not speaking in a two-person conversation—in what Goffman (1971, p. 235) calls the "structural" sense of the term. That is, it is an attempt to describe their placement in the stream of behavior.

The study is part of a program of investigation (Duncan, 1972, 1974; Duncan & Fiske, 1977; Duncan & Niederehe, 1974) whose purpose is to discover the organization of face-to-face interaction. The term *organization* reflects the assumption that just as language operates according to rules that give it a definite structure, so does the process of face-to-face interaction in which language ordinarily occurs.

The research of Duncan and his associates on the structure of interaction is based on detailed transcription of speech and body motion in two-person conversations. Exploration of these materials has led to the formulation of a set of hypothesized signals and rules that people apparently use to exchange speaking turns and otherwise regulate the flow of interaction in conversations. These rules depend on a distinction between the "speaker" (the person who holds the speaking turn)

This study is based on a dissertation submitted in partial fulfillment of the requirements for a doctoral degree in psychology at the University of Chicago. The author would like to acknowledge the support and guidance of his committee—Starkey Duncan, Jr. (Chairman), Donald W. Fiske, and Norman Bradburn.

The research was supported by National Science Foundation Grant SOC 74-24084 to Starkey Duncan, Jr., and Donald W. Fiske.

and the "auditor" (a person who is in the conversation without holding the turn). To hold the speaking turn is not the same as to emit speech sounds; in the conversations we have studied, brief pauses seldom if ever constitute relinquishment of the speaking turn, and it is possible for a person to talk without claiming the speaking turn (for example, to say things like "yeah" and "uh-huh").

Speaking Turns

Duncan (1972) hypothesized a turn signal composed of six separate cues in language, paralanguage, and body motion. If any one or any combination of these cues is displayed, the auditor may take the turn if he or she wishes to. The auditor is not required to take the turn when the turn signal is displayed; he or she merely has the option of doing so. There is a marked tendency for the turn signal to precede orderly (smooth) exchanges of the speaking turn, but it seldom precedes instances of "simultaneous turns" in which both participants attempt to hold the floor at the same time.

Complementary to the turn signal is the "gesticulation" signal. While the speaker is gesticulating, the auditor should not attempt to take the turn, regardless of whether the turn signal is displayed. The evidence for this formulation is that the auditor is much less likely to attempt the turn when the speaker is gesturing and that if the auditor does, the result is usually simultaneous turns, even when one or more turn cues are also present.

Back Channels

The turn signal and the gesticulation signal are both conceived to facilitate the smooth exchange of turns. In further development of the turn system, attention has been directed toward speaker–auditor interchanges that occur *during* speaking turns. Duncan (1974) reported a study of auditor "back channels" (head nods and statements such as "yeah" and "uh-huh") that explored some of the differences between back channels and turn attempts and related auditor back channels to the actions of the speaker.

Unlike turn attempts, auditor back channels are not suppressed by the speaker's gesticulation. In addition, back channels and turn attempts are distributed differently with respect to the boundaries of segments into which the conversations were divided for purposes of statistical analysis. It is likely that these segments reflect structural properties of speech and communicative body motion (Duncan & Fiske, 1977, discuss them in detail). Turn attempts usually occur exactly between segments, whereas back channels are more loosely distributed.

Another important distinction between auditor back channels and turn attempts is that they seem to be related to different sets of cues given by the speaker. Duncan (1974) hypothesized a speaker "within-turn" signal originally consisting of two cues: grammatical completion and turning of the head toward the auditor. Brunner (1977) has reanalyzed the data and found evidence for changing the head turn cue to simple head direction toward the auditor. Responses to the within-turn signal, like responses to the turn signal, are conceived to be optional; the speaker is not obliged to give a back channel, but may do so if a signal is present.

The thesis of the present study is that the placement of smile beginnings in conversations is closely parallel to that of back channels and that, in fact, smiling can be a type of back channel. This idea was suggested by the entirely serendipitous finding that most auditor smile beginnings were preceded by the within-turn signal. In order to claim, however, that the auditor's smile beginnings occupy a place that is similar to back channels in the structure of interaction, three other requirements must be met.

1. There must be an acceptable statistical relation between occurrence of a smile beginning and previous display of the within-turn signal.

2. Auditor smile beginnings must be more loosely distributed with respect to segment boundaries than auditor turn attempts are.

3. The auditor's smile beginning must not be suppressed by the speaker's gesticulation.

Method

Conversations and Transcription

The four conversations on which this report is based are a subset of the ones described by Duncan and Fiske (1977). Conversations 1, 2, and 3 are 7 minutes long. All three were between female law students and male social work students at the University of Chicago; the participants were paid volunteers who were previously unacquainted. Conversation 4 is 19 minutes long and, unlike the other three conversations, would have occurred whether or not it was videotaped. It was between two 40-year-old male psychotherapists from the Counseling Center at the University of Chicago. They were good friends and had known each other for about 10 years. The subject of their conversation was a client whom both of them had been seen recently. Duncan and Fiske give more detailed background information about these conversations. They refer to Conversations 1 through 4 as numbers 5, 6, 7, and 2, respectively.

In all four conversations, the participants were seated in adjacent chairs turned slightly toward each other, facing a video camera. The participants in the first three conversations were requested to get acquainted and carry on a short conversation, and in the fourth they were asked to continue a conversation that they had been unable to complete on a previous occasion.

The conversations have been transcribed in considerable detail, but for the present study, only the following actions were important: spoken syllables, completions of subject–predicate clauses, intonation (according to Trager & Smith's, 1957, system), gestures, head movements, and smiles. In this study, the term *smile* refers to apparent bilateral or unilateral contraction of the risorius and buccinator muscles. Each event was carefully located with respect to the other events in the conversation so as to produce a transcript in which the sequence of actions is represented, accurate to one syllable.

In transcribing body motion for this study, the author and a research assistant worked together with the goal of making a transcription on which they completely agreed; in cases of doubt, other people familiar with the transcription system were consulted. Typically, agreement between observers is very high without discussion, and previous studies of the reliability of the transcription system used in the present investigation have yielded a median kappa (Cohen, 1960) of .81 (roughly 95% agreement) between separate observers (Duncan & Fiske, 1977, p. 342).

Data Analysis

Unit of analysis. In order to assess behavioral regularities within an interaction, it must be divided into units to which scores are assigned. The reason is that in order to present evidence that some action, A, precedes B more often than one would expect by chance, it is necessary to know not only how many times A preceded B and how many times each action occurred separately but also how often each action did not occur. In the analyses to be reported here, the unit of analysis is a stretch of speech that can be as short as a single phonemic clause (Trager & Smith, 1957) and as long as an entire speaking turn.

The boundaries of the units of analysis (which will be called "segments" for convenience) occur after the boundaries of phonemic clauses that contain one or more of the following actions: unfilled pause, audible inhalation or exhalation, turning of the speaker's head toward the auditor, a drop in paralinguistic pitch or loudness, any pitch level – terminal juncture combination other than 2 2 | at the end of a phonemic clause, paralinguistic drawl on the final or the stressed syllable of a phonemic clause, termination of a gesture or relaxation of a tensed hand position by the speaker, use of a stereotyped expression such as "but uh" or "you know," or the completion of a grammatical clause consisting of a subject and predicate. Duncan and Fiske (1977) explain segments in much more detail.

In addition to serving as the basic units of analysis, segments are used to describe the distribution of events within an interaction. The locations of the auditor's actions with respect to segment boundaries can be represented in a fourfold typology. The four categories of location are the following:

1. Speech overlap—from roughly the middle to slightly before the end of the segment.

2. Pause—between the last syllable of the unit in question and the first syllable of the next unit.

3. Sociocentric sequence—before or during a sociocentric sequence such as "but uh" or "you know."

4. Postboundary—from the very beginning to roughly the middle of the segment after the one in question.

Statistics. Evidence for the relation between the speaker's within-turn signal and the auditor's smile beginning will be presented in a fourfold table where the columns indicate presence versus absence of the signal, and the rows indicate presence versus absence of a subsequent smile beginning by the auditor. If the results are parallel to those obtained for back channels, and the speaker's within-turn signal permits an auditor smile beginning but does not require one, almost every auditor smile beginning should be preceded by the signal. If the signal operated perfectly, the cell representing auditor smile beginning in the absence of the within-turn signal would be zero. There is no requirement, however, that the other cell in that diagonal (failures to respond to the signal) be zero or even have a particularly low frequency; permissive signals allow the option of not responding.

Consequently, the most useful index of association between signal and response for the table just described is one that reaches its maximum when only one cell is empty. The statistic Q (described by Yule, 1900, and further developed by Goodman & Kruskal, 1954, 1959, 1963, 1972) has this property: It equals

1.0 or −1.0 when one cell or both cells on one diagonal of a 2 × 2 table equals zero. The *Q* also has the advantage of being a true index of association, directly interpretable as percentage of improvement in predicting the dependent variable when the independent variable is known. The standard error of *Q* can be calculated, and the hypothesis that *Q* is significantly different from zero may be tested by dividing *Q* by its standard error and referring the result to the normal curve. The *Q* and its two-tailed probability value will be reported for all the 2 × 2 tables in this article.

Replication. Since the results to be reported here are the products of very thorough exploration rather than hypothesis testing, they must be replicated in order to ensure that they do not merely reflect random contingencies in the data. I have used Conversations 1 and 2 for exploration and Conversations 3 and 4 for replication. Although pooled data are reported for both the exploratory and replication samples, the results for all eight participants were examined separately to make sure that the same trends held for all individuals.

The analyses to be reported do not include segments with auditor turn attempts or smiles continued from the previous segment. Segments with turn attempts were excluded because when a person smiled as he or she claimed the speaking turn, it was often impossible to decide whether to call the action a speaker smile or an auditor smile. Segments with auditor smile continuations were excluded because the auditor could not begin to smile when he or she was already smiling.

Results

The Within-Turn Signal

Previous research has shown that the speaker's within-turn signal regularly precedes auditor back channels whose location with respect to segment boundaries is late or between units, but not those which are early or occur before or during a sociocentric sequence. This is also the case for auditor smile beginnings.

Table 1 shows that in both the exploratory and replication conversations, the speaker's within-turn signal (composed of grammatical completion or head direction toward the auditor or both) preceded a high percentage of the auditor's late and between-units smile beginnings and was significantly related to their occurrence. In Conversations 1 and 2, 23 of 24, or 95.8%, of the auditor's smile beginnings occurred while the within-turn signal was present. For the 2 × 2 table relating the

Table 1
Relationship Between Display of Speaker's Within-Turn Signal and Subsequent Display of Auditor Smile Beginning

Auditor's smile beginning	Speaker's within-turn signal: Proportion of segments with signal absent	Speaker's within-turn signal: Proportion of segments with signal present	Row total of segments
Pause and postboundary smiles: Exploratory sample[a] (Conversations 1 and 2)			
Absent	.27	.72	153
Present	.04	.96	24
Pause and postboundary smiles: Replication sample[b] (Conversations 3 and 4)			
Absent	.26	.74	487
Present	.00	1.00	15
Speech overlap and sociocentric sequence smiles[c] (Conversations 1, 2, and 4)			
Absent	.23	.77	697
Present	.33	.67	12

[c] $Q = -.26$, $p = .36$.

auditor's smile beginning to prior display of the speaker's within-turn signal, $Q = .79$, $p = .00006$. In Conversations 3 and 4, all 15 between-units and late auditor smile beginnings happened in the presence of the within-turn signal. $Q = 1.0$, and the associated probability cannot be calculated because the standard error is zero.

The bottom third of Table 1 shows that there is an insignificant negative relation between presence of the speaker's within-turn signal and auditor smile beginnings located at speech overlaps or sociocentric sequences. Similar results are reported by Duncan and Fiske (1977) for vocal back channels and head nods that occur in these locations.

Effect of Speaker's Gesticulation

Auditor turn attempts are suppressed by the speaker's gesticulation, but back channels are not. To test whether smile beginnings are also unaffected by the speaker's gesticulation, data were arranged in 2 × 2 tables where the rows indicated presence versus absence of the speaker's gesticulation and the columns indicated presence versus absence of the auditor's smile beginning. In the exploratory sample (Conversations 1 and 2), the auditor's smile and the speaker's gesticulation were not significantly related ($Q = -.36$, $p = .14$).

In the replication sample (Conversations 3 and 4), it seemed at first that the auditor was somewhat less likely to smile while the speaker was gesticulating ($Q = -.45$, $p = .04$). These are not strong results, but it is strange that smile beginnings should show a structural similarity to turn attempts rather than back channels, particularly when this did not happen in the exploratory study.

Examination of the data from Conversations 3 and 4 separately indicates that there is virtually no relationship between the speaker's gesticulation and the auditor's smile in either conversation. Conversation 4 has a low rate of auditor smiling and a high rate of speaker gesticulating; Conversation 3 has a relatively high rate of auditor smiling and an extremely low rate of speaker gesticulating. Consequently, although there is no relation between the speaker's gesticulation and the auditor's smile beginning in either conversation, an artificial one appears when data from the two are pooled. This finding shows how important it is to examine subsets of data separately before combining them.

Table 2
Locations of Auditor Smile Beginnings and Turn Attempts With Respect to Segment Boundaries

Location	Auditor turn attempts: Frequency	Auditor turn attempts: %	Auditor smile beginnings: Frequency	Auditor smile beginnings: %
Exploratory sample (Conversations 1 and 2)				
Speech overlap	16	15.4	8	24.2
Pause	84	80.8	16	48.5
Postboundary	2	1.9	8	24.2
Sociocentric sequence	2	1.9	1	3.1
Total	104		33	
Replication sample (Conversations 3 and 4)				
Speech overlap	13	22.0	2	11.8
Pause	40	67.8	9	52.9
Postboundary	2	3.4	6	35.3
Sociocentric sequence	4	6.8	0	0
Total	59		17	

Table 2 compares the distributions of auditor smiles and turn attempts with respect to segment boundaries. Auditor smile beginnings are less concentrated in the "pause" location (the same finding that has been obtained for back channels), although this tendency is not as pronounced in the replication study.

Discussion

The organization of auditor smile beginnings in these conversations is parallel to that of back channels. They are both consistently preceded by the speaker's within-turn signal, they are both unaffected by the speaker's gesticulation, and they are both more loosely distributed than turn attempts with respect to segment boundaries. Taken together, these results are grounds for placing auditor smile beginnings in the category "back channel," along with nods and statements such as "yeah" and "uh-huh."

Nods and vocal back channels seem intuitively to belong together, because they both seem to say, in effect, "Yes, you are understood. Proceed." Although it is not immediately obvious that smiles belong in this category, I believe that auditor smile beginnings, like auditor back channels, make communication more efficient by providing the speaker with feedback.

The idea of communicative efficiency lies behind much of the turn system, though it has not been given a great deal of emphasis. For example, the turn signal was constructed so that at least one cue would be present before each smooth exchange of turns, but not before instances of simultaneous turns. The reasoning was that a system of rules for taking speaking turns ought to result in smooth exchanges when it is working properly, because human beings have only a limited capacity to send and receive information simultaneously.

The people who have written about the actions that we call back channels generally agree that the auditor uses them to provide the speaker with information. There is less unanimity, however, concerning the exact sort of information that back channels convey. Fries (1952, p. 49) suggests that they are primarily signs of attention and involvement in the conversation. Yngve (Note 1) agrees, but proposes that they are also "very important in providing for monitoring of the quality of the communication" (p. 568). Dittmann and Llewellyn (1967) imply that in addition, they are sometimes used for directly requesting further information or explanation (this is consistent, of course with Duncan's treatment of short questions as back channels).

Kendon (1967) distinguishes between "point granting" and "assenting" signals, both of which we would describe as back channels. This distinction merely reflects the fact that usually the auditor's feedback indicates that he or she is following what the speaker says, and sometimes it also indicates agreement. It is important to mention in this connection that head shakes and verbal statements of disagreement were treated as back channels in the present study and in Duncan's earlier investigations. This was done mostly on intuitive grounds (they "felt" like back channels), but the implicit rationale was that feedback need not always be positive in tone, although it usually is.

There is a consistency among the various sorts of information that back channels are supposed to provide. I would like to suggest that back channels (including smiles) give the speaker feedback on three levels. On the first level, back channels signal the auditor's involvement and participation in the interaction. They indicate that the auditor is attending to what the speaker says and that a conversation, not a monologue, is occurring.

On the second level, back channels provide information about the auditor's level of understanding, allowing the speaker to adjust his or her communicative endeavor so as to get the ideas across efficiently. "Mhm's" and head nods tell the speaker that the message is being decoded successfully; when the location of these signals is "speech overlap" (before the end of a segment of speech is reached), they may indicate that the auditor is "ahead" of the speaker and a little less elaboration would be in order; a puzzled or blank look may indicate that more information is needed (no work has been done on the actions that signify the auditor's lack of understanding, except for clarifying questions).

On the third level, back channels can signal the auditor's personal response to what the speaker has just said. This might mean agreement or disagreement, shock, amusement, scorn, or any number of other reactions. In general, if an action functions on a higher level it also functions on the ones below it; any indication of a personal reaction implies understanding (or the lack of it), and any indication of a degree of understanding implies some involvement in the conversation. Smiles are higher level back channels, providing feedback on all three levels. They indicate a positive personal reaction (often merely politeness), as well as understanding of the preceding statement and participation in the conversation.

We do not know how far the results of the present investigation can be generalized. The findings of the exploratory study were fully

replicated, which indicates that at least they are not unique to a particular conversation. Definitive information about the limits within which they hold can be provided only by further studies of smiling in which many people are observed in many different settings.

Motoric and Symbolic Mediation in Observational Learning

Seymour M. Berger, Linda L. Carli, Kathy S. Hammersla,
Judith F. Karshmer, and M. Estela Sanchez
University of Massachusetts—Amherst

The observers' motoric and symbolic representations of a model's behavior are important mediators in observational learning. The observers' *spontaneous* use of these mediators may be influenced by their familiarity with responses performed by a model and by their intention to learn these responses. Unfamiliar observers do not have symbolic codes available for the model's responses, so they may rely on motor mimicry. Familiar observers have symbolic codes available, so they may employ these codes and, possibly, motor mimicry as mediators. Spontaneous mediation may also depend on whether observers intend to learn these responses. Experiments revealed that familiar observers use motoric and symbolic mediators, whereas unfamiliar observers primarily use motor mimicry. Symbolic coding facilitates familiar observers' but not unfamiliar observers' learning; unfamiliar observers' learning is related to motor mimicry. Intention to learn increases motor mimicry but not symbolic coding. An interpretation is offered for the observers' pervasive use of motor mimicry.

Bandura (1974) has emphasized the role of imaginal and verbal coding, and rehearsal of these symbolic codes, in observational learning. Berger (1966, 1968), on the other hand, has focused on the role of motor mimicry, motor rehearsal, and conditioning in observational learning. Studies supporting these analyses, however, either have not examined the observers' *spontaneous* use of different forms of mediation or else have *instructed* observers to use different mediators (e.g., Bandura, Grusec, & Menlove, 1966; Bandura & Jeffery, 1973; Berger, Irwin, & Frommer, 1970; Bernal & Berger, 1976; Gerst, 1971; Jeffery, 1976). The following experiments examine some conditions that affect the observers' spontaneous motoric and symbolic mediation, and the relationship between these mediators, in an observational learning situation.

The authors are listed in alphabetical order. The authors involved in each experiment are identified separately in the report of each experiment.

Experiment 1: Letter Code Availability and Learning Instructions [1]

Bandura (1974) argues that observers represent a model's behavior through symbolic codes and that these codes guide subsequent motoric reproduction of the model's behavior. This analysis assumes that observers are able to code and that the response components already exist in the observers' behavioral repertoire. If observers cannot symbolically code because there is insufficient time for them to employ appropriate symbolic codes, then observers may attempt some other form of mediation, such as mimicry, in order to represent

[1] The authors of Experiment 1 were Seymour M. Berger and Kathy S. Hammersla. A portion of this experiment was presented under the general title of this article at the annual convention of the American Psychological Association, Toronto, Canada, in August 1978. This project was formulated, with the assistance of Norbert Vanbeselaere, while the first author was a Fulbright–Hays Senior Research Scholar at the Laboratory for Experimental Social Psychology, Catholic University of Leuven, Belgium. The authors wish to thank Margo McMahon for her assistance in selecting the hand signals and in checking the experimenter's reliability.

the model's behavior. Furthermore, if the response components of the model's behavior are not part of the observers' repertoire, these components may be acquired during the exposure period through the observers' mimetic practice. Thus, mimicry may facilitate learning for observers who are unable to symbolically code and/or unable to perform the appropriate response components.

When observers have symbolic codes and appropriate response components available, there appears to be no need for them to actually mimic the model; in this case, symbolic codes would *compensate* or substitute for mimicry, and mimicry would be reduced or not occur at all. It also is conceivable, however, that motoric and symbolic mediators *complement* rather than compensate for one another. In this case, observers would engage in both types of mediation. Motoric and symbolic mediators may be elicited directly by the model's behavior, or observers may use both types of mediation because they have found, through past experience, that using multiple mediators is more effective for learning than relying on a single form of mediation.

Half of the observers in this experiment were familiar with the manual alphabet for the deaf and half were not. It has been shown that observers tend to overtly mimic these gestures and that such mimicry is positively correlated with observer learning (e.g., Berger, 1966). If the compensatory theory of mediation is correct, then observers who know the manual alphabet can use the letter associated with each gesture as a mediator; therefore, they should engage in less overt mimicry than observers who are unfamiliar with the alphabet. If the complementary theory of mediation is correct, then familiarity with the manual alphabet should not be associated with a reduction in overt mimicry.

In addition to varying response familiarity, observers were instructed either to learn from the model's performance or merely to watch. This was done for two reasons: (a) The observers' spontaneous use of motor and symbolic mediators may depend on whether they intend to learn; and (b) we wanted to provide a comparison with previous research.

Method

Subjects. Thirty-two undergraduates at the University of Massachusetts—Amherst were included in this study.[2] Twenty-five of these subjects received course credit for their participation; seven subjects were volunteers from a course in sign language.

Procedure. Subjects were run individually and were assigned alternately to either the learning or watch-only conditions. Since observers tend not to overtly mimic the model if they are being watched (Berger, 1966), observers were led to believe that they were alone.

Briefly, observers were told that the experimenter had inadvertently signed up two subjects for the same time period, but that the observer could watch the experiment over closed-circuit television from an adjacent "recording" room. After being seated in the recording room, half of the observers were told to watch the television monitor and to follow the instructions given to the subject in the other room. Since the experiment was described as a study of nonverbal learning, the experimenter explained that she would return to test the observer after all the learning materials were presented. The other half of the observers were told that they would receive participation credit if they merely watched the experiment on their monitor. (Seven observers could not receive credit. This presented no problem with three subjects who were assigned to the learning instruction condition, since they had volunteered anyway. The remaining four subjects were in the watch-only condition, and they were told they could help the experimenter by evaluating her performance.)

The experimenter explained that she would turn on the camera when she returned to the subject in the adjacent room. Upon returning to that room, she started the videotape player and seated herself at the one-way mirror in order to record the observer's mimicry. The observer was led to believe that the mirror was covered, but the experimenter could see the observer without being noticed.

The videotape showed the experimenter reentering the adjacent room and giving the instructions to the other subject (model). These instructions stated that the subject had to learn pairs of gestures and that the subject would be tested after the pairs were presented. The pairs were presented by means of a slide projector. Each gesture appeared on a separate slide for 5 sec, with a blank 5-sec period inserted between each pair of gestures. The pairs were gestures associated with *X* and *Q*, *R* and *A*, *P* and *Q* and *K* and *B* in the manual alphabet. The observer

[2] Forty-nine subjects were recruited for this study. Eight of these subjects were eliminated because of procedural errors or because procedural requirements could not be met. The remaining 41 subjects formed the pool from which the 32 observers were selected as explained in the procedure.

saw a same-sex model perform each gesture once while it was projected on the screen.

After all the pairs were shown, but before the subject was tested, the experimenter explained that she had to go into the next room for a moment. The videotape was stopped, as if the camera had been turned off. She returned to the recording room and asked the observer to show her all the pairs that the observer could recall. After noting the observer's response, she asked the observer to complete a questionnaire.

Observers were asked to indicate how familiar they were with the manual alphabet and (with the aid of printed drawings of the gestures used) to indicate in separate items which gestures they actually performed, which they formed images of, which they identified by letter, and which they represented in some "other" way (e.g., words, numbers, etc.).[3] The final questions dealt with the observers' understanding of the instructions and whether they were "suspicious about the instructions . . . received at the time they were given or while . . . watching the TV set"; if observers responded affirmatively, they were to answer the following question: "What were you suspicious about?"

According to their questionnaire responses, 16 of the 41 observers knew some or all of the gestures from the manual alphabet. Seven of these observers were volunteers from the sign language course; the remaining nine familiar observers may have been attracted to the experiment because it was described as a study of nonverbal learning involving gestures. Eight of these familiar observers (six females and two males) were instructed to learn, and the remaining eight observers (all females) were instructed to merely watch. In order to obtain equal numbers of unfamiliar observers, eight observers (six females and two males) under instructions to learn and eight observers (six females and two males) under instructions to merely watch were randomly selected from the remaining pool of 25 unfamiliar observers.

Results

The number of different gestures performed was used as a dependent measure in this experiment (and the experiments that follow), rather than total amount of performance, because the former measure was used previously (Berger, 1966) and the two measures are highly correlated (.85). The experimenter's records of different gestures performed correlated .98 ($p < .001$) with an independent assessment by another person during a pretest reliability check and .73 ($p < .001$) with the observers' self-reported mimicry of different gestures in this experiment.

In general, the experimenter recorded more mimicry of different gestures ($M = 5.00$) than observers reported ($M = 3.03$). For observers who were seen to mimic or reported mimicking, this difference is highly significant, $t(24) = 4.40$, $p < .001$. Observers apparently underestimated the number of different signals they performed.

The data did not meet the criteria for analysis of variance (ANOVA). The most serious violation was the lack of variability in certain cells involving unfamiliar observers. Therefore, nonparametric tests were used to verify each significant effect found in the ANOVAS, and only those effects which were supported by the nonparametric tests are reported below. The results of the F tests are reported, and the significance levels obtained from the nonparametric tests are reported in parentheses next to F-test levels. All significance tests are two-tailed.

Self-reported mediation. The mixed design ANOVA revealed that familiar observers engaged in more total mediation than unfamiliar observers, $F(1, 28) = 34.16$, $p < .001 (< .002)$, and that there were differences, $F(3, 84) = 7.56$, $p < .001 (< .01)$, among the observers' uses of the various mediators (i.e., mimicry, images, letters, or "other"). These main effects, however, have to be interpreted in terms of the Mediators × Familiarity, $F(3, 84) = 3.30$, $p < .05$, and the Mediator × Learning Instruction, $F(3, 84) = 4.04$, $p < .01$, interactions.

The means for the Mediation × Familiarity interaction are reported in Table 1, along with the percentages of observers who engaged in each type of mediation. A Newman-Keuls test of these means indicated that familiar and unfamiliar observers did not differ in their mimicry or in their use of "other" mediators. Familiar observers used more im-

[3] There were two series of questions regarding the observers' mediational activities. The first series asked about mediation during the video presentation, whereas the second series dealt with mediation following the presentation. Since the observers' mimicry following the presentation may have been influenced by the observers' expectation that the experimenter would return and see them performing, the questionnaire responses to the second series were excluded from analysis in Experiments 1 and 2 because they could have been influenced by this situational artifact.

Table 1
Mediation × Familiarity Interaction: Means and Percentages

	Mediator									
	Mimicry		Images		Letters		Other		Total	
Observer	*M*	%	*M*	%	*M*	%	*M*	%	*M*	%
Unfamiliar	2.81	69	.44	13	0	0	.31	13	.89	8
Familiar	3.25	69	3.38	75	2.75	63	1.25	44	2.66	10

Note. There were eight gestures, so each mean could range between 0 and 8.

ages, $\alpha = .01(<.02)$, and more letters, $\alpha = .01(<.002)$, than unfamiliar observers.

Familiar observers engaged in more mimetic and imaginal mediation than "other" forms of mediation, $\alpha = .05(<.05)$, for both comparisons. None of the other differences between mediators for familiar observers was significant.

Unfamiliar observers used mimicry more than images, letters, or "other" mediators, $\alpha = .01(<.01)$, for each comparison. There were no significant differences between images, letters, and "other" mediators for unfamiliar observers. These observers tended to employ mimicry rather than symbolic mediators.

This analysis supports the complementary theory of mediation, because symbolic coding did not reduce motor mimicry. Familiar and unfamiliar observers engaged in about the same amount of mimicry even though familiar observers employed significantly more imaginal and letter coding.

The Newman-Keuls test showed that the Mediator × Learning Instruction interaction was produced by observers who were instructed to learn engaging in more mimicry than any other form of mediation by these observers or by the watch-only observers, $\alpha = .01(<.01)$, for all comparisons. Table 2 presents the means for this interaction along with the percentages of observers who engaged in each form of mediation. There were no differences in symbolic mediation as a function of learning instructions. Since the instruction to learn increased motor mimicry but not symbolic mediation, it appears that observers believed that mimicry would facilitate their learning more than symbolic mediation.

Observed mimicry. The ANOVA based on the experimenter's records revealed only a significant main effect of learning instructions, $F(1, 28) = 20.14$, $p < .001(<.002)$, and no interaction with familiarity. Observers who were instructed to learn performed more different gestures ($M = 7.06$) than the watch-only observers ($M = 2.94$). This finding supports the results of the self-report analysis regarding the effect of instructions to learn.

Observer learning. The ANOVA of the number of pairs learned yielded only a main effect for familiarity, $F(1, 28) = 10.51$, $p < .005(<.02)$, and no interaction with learning instructions. Familiar observers learned more

Table 2
Mediation × Learning Instruction Interaction: Means and Percentages

	Mediator									
	Mimicry		Images		Letters		Other		Total	
Condition	*M*	%	*M*	%	*M*	%	*M*	%	*M*	%
Watch only	1.62	44	1.88	50	1.06	25	.94	31	1.38	81
Learning instructions	4.44	94	1.94	38	1.69	38	.62	19	2.17	100

Note. There were eight gestures, so each mean could range between 0 and 8.

pairs ($M = 1.69$) than unfamiliar observers ($M = .44$).

Correlations between mediators and between mediators and number of pairs learned. None of the correlations between the self-reported mediators was significant. Unfamiliar observers' self-reported mimicry correlated .62 ($p < .05$) with pair learning, and these observers' observed mimicry correlated .53 ($p < .05$) with pair learning. For familiar observers, letter coding correlated .55 ($p < .05$) with pair learning, and their imaginal coding correlated $-.51$ ($p < .05$) with pair learning. Because of a lack of variability, it was not possible to correlate unfamiliar observers' symbolic coding (i.e., images, letters, and "others") with pair learning. Familiar observers' "other" coding, self-reported mimicry, and observed mimicry were not significantly correlated with pair learning.

These correlations suggest that in the absence of other forms of coding and well-practiced responses, motor mimicry prevails as an effective mediator in learning; but given a readily available code that is associated with well-practiced responses, symbolic coding is more effective than mimicry.

Manipulation checks and suspiciousness. Most observers correctly recalled the instructions given them. Approximately one third of the observers instructed to learn and one third of the observers instructed to merely watch reported being suspicious. The major sources of suspicion were the cover story, particularly with regard to whether the other subject was real and whether observers were being watched. None of the observers guessed the actual purpose of the study.

Discussion

The finding that unfamiliar observers relied almost exclusively on motoric mediation contrasts sharply with the familiar observers' use of a variety of mediators. Unfamiliar observers could have used imaginal and other forms of coding, but they did not do so. A possible explanation for the familiar observers' mediational behavior, as well as for similar findings in the studies that follow, will be presented in the final section of this article.

There was a significant negative correlation between imaginal coding and learning, and a tendency (which was not significant) for imaginal coding to be negatively correlated ($-.44$) with letter coding for familiar observers. Apparently, letter coding was a more effective form of mediation than imaginal coding for these observers. Perhaps familiar observers who chose to code imaginally did not have time to letter code as well, and their learning suffered as a consequence. Other studies report that imaginal coding facilitates observational learning (e.g., Gerst, 1971; Ito, 1975; Jeffery, 1976). These studies may have provided more time for mediation, but they also differed from the present study in several other ways. Therefore, it is not possible to identify the basis for these inconsistent findings.

Experiment 2: Symbolic Mediation With Relatively Available Verbal Codes [4]

In Experiment 1, familiar observers' learning was positively correlated with letter coding. In order to determine whether this correlation reflected a causal relationship, an attempt was made in Experiment 2 to bring the observers' use of verbal coding under experimental control by either exposing observers to a verbal coding model (verbal coding condition) or instructing them to use verbal codes to help them learn the model's behavior (instruction condition).

Exposure to a model who engages in overt verbal coding may have one or more consequences for observer mediation and learning. The model's coding behavior may suggest a learning strategy to observers who might not otherwise use verbal coding. Furthermore, the model's coding behavior may provide useful codes to observers who intend to use verbal codes but cannot think of any. Finally, it also is possible that the model's coding behaviors will elicit unintentional imitation and, thereby, facilitate observational learning. No matter which of these processes is involved, there is

[4] The authors of Experiment 2 were Seymour M. Berger, Linda L. Carli, Judith F. Karshmer, M. Estela Sanchez, and Kathy S. Hammersla.

ample reason to believe that a verbal coding model will increase the observers' verbal coding.

Instructing observers to code verbally is another way to increase the observers' coding behavior, provided that they have an available verbal code. Since several studies of observational learning have used such instructions (e.g., Bandura et al., 1966; Bandura & Jeffery, 1973; Gerst, 1971; Jeffery, 1976; van Hekken, 1969), it seemed desirable to compare this treatment with treatments involving a verbal coding model and a nonverbal coding model.

A secondary purpose of this investigation was to demonstrate that the mimicry phenomenon has some degree of generality. Instead of gestures from the manual alphabet, gestures commonly used in United States culture were selected, because all observers probably had performed these gestures previously and would have a readily available word or phrase that they could associate with each gesture (e.g., "come here," "good-bye," "stop"). Thus, observers in this experiment were comparable to familiar observers in Experiment 1 in that they had a highly salient symbolic code available for mediation.

It was hypothesized that observers exposed to a model who performed the gestures but did not engage in overt verbal coding (nonverbal coding condition) would use less verbal coding and would recall fewer pairs and fewer responses than observers in either the verbal coding or instruction conditions. It could be argued, of course, that almost all (if not all) observers would respond to the gestures with the verbal codes regardless of the treatments they received, because the verbal codes are readily elicited when the gestures are performed. This ceiling effect was not expected to occur, however, because the model performed the responses relatively rapidly, thus reducing the observers' time to react with an appropriate verbal code. No differences were expected between conditions in the amount of mimicry, since the model's performance was the same in all conditions and Experiment 1 demonstrated that observer mimicry was independent of the observers' use of symbolic coding.

Method

Subjects. Sixty undergraduates were recruited from a variety of undergraduate courses in psychology at the University of Massachusetts—Amherst.[5] Subjects received extra course credit for their participation.

Procedure. Observers were run individually by one of four different female experimenters. Each experimenter ran five subjects in each of the three conditions.

The procedure for this experiment was similar to that used in Experiment 1. Observers were asked to learn pairs of gestures and were told that two subjects were being run at the same time for purposes of efficiency. The gestures would be presented by means of videotape to the subject in the adjacent room, but the observer would be able to see the presentation over closed-circuit television, because a camera had been installed in the adjacent room. The observer was seated in front of a small television monitor located directly in front of a one-way mirror that appeared to be completely covered.

After giving the instructions, the experimenter left the room, explaining that she had to turn on the camera and the videotape recorder from a third room (observers saw this room and a videotape deck when they arrived for the experiment). She stated that she would return to test the observer after the presentation. The experimenter actually went to the adjacent room, turned on the videotaped model presentation, and positioned herself behind the one-way mirror, which afforded her a clear view of the observer through a small uncovered space at the bottom of the mirror.

After recording any gestures performed, she turned off the videotape, returned to the observer's room, asked the observer to perform the pairs of gestures, and recorded all gestures correctly performed. Observers then completed a questionnaire similar to the one described in Experiment 1, but with drawings of the new gestures. On this questionnaire, observers also were asked to specify which gestures they associated with words and the words they used.

The videotaped gesture presentation began with a medium close-up picture of a large television set on top of a desk. This videotaped television set was used to present additional instructions and gestures, which were actually performed. The instructions, given by a male voice, indicated that the experiment was about to begin. The subject would see three pairs of gestures. Each gesture would be presented separately, and the first member of each pair would be followed by the second member of that pair, with a blank

[5] Because incomplete records were kept regarding the sex of the subjects, the distribution of males and females cannot be given with complete confidence. It appears that there were an equal number of males and females in each condition. Nine additional subjects were run, but these were excluded from the analysis either because their data were uninterpretable or because they did not meet procedural requirements

space appearing between the pairs of gestures. At the end of these instructions, the male voice asked the subject to get ready. At this point, the female model (presumably, the other subject) moved into the picture that the observer saw, as if she were leaning toward the television set in front of her to get a better view. In all conditions, this model performed each of the gestures immediately after it was presented.

The six gestures used were culturally common signs for "come here" (a slightly closed hand with a beckoning index finger), "OK" (index finger and thumb forming a circle, with the remaining fingers vertical and slightly separated), "good-bye" (thumb stationary while the remaining fingers bent down and up), "you" (index finger pointing directly toward the viewer, with remaining fingers forming a fist), "stop" (palm facing viewer, with all fingers vertical, thrust toward the viewer), and "two" (index and middle finger forming a vertical *V*, with thumb overlapping remaining bent fingers).

The gestures were presented in this sequence so that each gesture appeared on the screen for about 2 sec. There was a 2-sec interval between pair members and a 3½-sec interval between the pairs.

Observers were assigned to one of three conditions in the order in which they appeared for the experiment. Observers assigned to the verbal coding condition (VC) heard the female model say the word associated with the gesture as she performed each gesture. Observers assigned to either the nonverbal coding condition (NC) or the instruction condition (IC) saw a tape in which the model performed each gesture but did not say anything; however, IC observers received the following instruction from the experimenter prior to the videotaped presentation: "Each gesture can be associated with a common English word. Use the word you associate with each gesture to help you learn the pairs."

Results

The reliability of the four experimenters' records of the number of different gestures performed was assessed by having two pairs of these experimenters watch a different set of observers. The reliability correlation for each pair of experimenters was .99 ($p < .001$), based on samples of 10 and 15 observers. The experimenters' records correlated .77 ($p < .001$) with the observers' self-reported mimicry of different gestures.

As in Experiment 1, observed mimicry of different gestures ($M = 4.13$) was greater than self-reported mimicry ($M = 3.37$). This difference, based on observers who mimicked (observed or reported), was significant, $t(39) = 2.63$, $p < .02$.

The observers' self-reported use of "other" mediators (e.g., numbers, letters, etc.) was not included in the data analysis because only four observers reported using "other" mediators (one in VC, one in IC, and two in NC). This also eliminated the ANOVA problem encountered in Experiment 1, because of cells having little or no variability. All significance tests are two-tailed.

Self-reported and observed mediation. The mixed design ANOVA yielded a main effect for mediators, $F(2, 114) = 5.89$, $p < .01$, and a significant Conditions × Mediators interaction, $F(4, 114) = 3.97$, $p < .01$. The means for these significant effects are reported in Table 3, along with the percentages of observers using the mediators.

The main effect for mediators must be interpreted in terms of the Conditions × Mediators interaction. In order to carry out 18 preplanned comparisons of the means involved in this interaction, the Bonferroni *t* (see Myers, 1978) familywise error rate was set at

Table 3
Means and Percentages for Self-Reported Mediation: Experiment 2

Condition	Mediator: Mimicry *M*	Mimicry %	Images *M*	Images %	Words *M*	Words %	Total *M*	Total %
Verbal coding	2.75	65	2.65	60	4.50	95	3.30	100
Nonverbal coding	3.85	90	1.80	65	2.25	75	2.63	100
Instruction	3.50	90	3.00	75	4.20	90	3.57	100
Total	3.37	82	2.48	67	3.65	87	3.17	100

Note. There were six gestures, so each mean could range between 0 and 6.

.10; thus the alpha level for any specific comparison was .006. Looking first at the pattern of mediation *within* each condition, one can see that VC observers used significantly more words than either images or mimicry; the difference between images and mimicry was not significant. The NC observers used significantly more mimicry than images; their use of mimicry and images did not differ significantly from their use of words. There were no significant differences in the IC observers' use of these mediators. Thus, each condition manifests a somewhat different pattern of self-reported mediation; the observers' use of images tended to be relatively low in all conditions, which accounts for the mediator main effect.

The comparisons *across* conditions for particular mediators are most relevant to the main purpose of the study. As predicted, NC observers used significantly fewer words than either VC or IC observers; the difference between VC and IC observers' use of words was not significant. There were no significant differences in the comparisons between conditions for images or for mimicry. (This is a somewhat conservative test, because comparisons within the rows are not independent of the comparisons within the columns of means reported in Table 3.)

An ANOVA using the experimenters' reports of observed mimicry also showed no significant difference between conditions, $F(2, 57) = 1.26$. Therefore, the hypothesis regarding mediation is supported, because exposure to a verbal coding model or being given instructions to use a verbal code facilitated the observers' use of verbal coding as compared to observers who were exposed to a nonverbal coding model. Also, it is clear that observers spontaneously mimic these cultural gestures, so mimicry is not limited to gestures from the manual alphabet.

A separate analysis was conducted to determine whether observers who used verbal codes tended to use *exactly* the same words for gestures as the VC model. The mean percentage of words that were exactly the same as the VC model's words was 90% for VC observers, 66% for NC observers, and 67% for IC observers.

Observer learning. The ANOVA compar the number of pairs learned between cond tions yielded $F(2, 57) = 2.79$, which is no significant. Nevertheless, comparisons betwee pairs of conditions were carried out, becaus specific predictions were made regarding th pattern of differences. The trend in the mea was as predicted. The mean number of pai learned by NC observers (1.05) was less tha the mean number of pairs learned by VC ob servers (1.55) and by IC observers (1.75 However, the Bonferroni t with a familywis error rate set at .10 for the comparison o three means revealed that only the differenc between the number of pairs learned by N and IC observers was significant ($\alpha = .03$ f each specific comparison).

A second measure of learning involve merely counting the number of different ge tures recalled by each observer, regardless o whether they were properly paired. Th ANOVA for this measure of learning yielded highly significant conditions effect, $F(2, 5$ $= 8.55$, $p < .001$. The NC observers recalle significantly fewer gestures (3.95) than eithe the VC observers (4.85) or the IC observer (5.00) (the VC and IC observers' learnin was not significantly different). These wer highly significant differences: The error ra for each comparison was less than .003, usin the Bonferroni t. The learning hypothesis i strongly supported by this analysis of num ber of gestures learned and is partially sup ported by the analysis of pair learning.

Manipulation checks and suspiciousnes The manipulation checks indicated that mos observers correctly recalled the instruction they received and the model's performance gestures and words (in the VC condition).

As in Experiment 1, approximately on third of the observers indicated that the were suspicious. These observers were aske "What were you suspicious about and whe did you become suspicious?" Most of thes observers questioned whether the other su ject was real. Some observers reported th they were suspicious about all psychologic experiments. A few observers thought some one might be watching them; two of these thought that someone might be watching see how they learned.

scussion

The lack of a clear conditions main effect for number of pairs learned is somewhat surprising given the highly significant conditions main effect for number of gestures learned. Perhaps a stronger conditions effect for pair learning might have been achieved if the learning task had included more pairs, longer exposure to the gestures, or a longer interval between the pairs of gestures. Several observers complained that the exposure time was too short for them to think of words and to make the necessary associations; other observers complained that the distinction between pairs was not clear in the videotaped presentation.

Experiment 3: Symbolic Mediation With Relatively Unavailable Verbal Codes [6]

In Experiments 1 and 2, the use of symbolic mediators (i.e., letters and words, respectively) was related to increased learning. This relationship existed only when observers had symbolic codes available for the model's behavior. Experiment 3 investigated the influence of verbal mediators when observers had no prior symbolic (verbal) code for the model's behavior.

In Experiment 1, the unfamiliar observers did not engage in symbolic coding; their learning was related to their mimicry of the model's responses. Without prior practice in performing the model's responses and without salient verbal codes for these responses, it seemed unlikely that unfamiliar observers would profit from the use of symbolic codes.

In order to test this hypothesis, observers who were unfamiliar with the manual alphabet were instructed to learn certain pairs of gestures from the alphabet. Half of the observers also were instructed to associate words with gestures to help them learn (instructed condition); the remaining observers did not receive these instructions (noninstructed condition). Observers in the instructed condition were expected to engage in more verbal mediation than observers in the noninstructed condition, but no differences were expected between these conditions in learning. Furthermore, since mimicry was found to be unaffected by verbal mediation in Experiments 1 and 2, no differences in mimicry were expected. Observers in the instructed condition, however, were expected to engage in more imaginal and "other" types of coding than those in the noninstructed condition, because the results of Experiments 1 and 2 seemed to indicate that those observers who engaged in symbolic coding also engaged in imaginal and "other" forms of coding.

Method

Subjects. Forty undergraduates were recruited from a variety of undergraduate summer session courses at the University of Massachusetts—Amherst.[7] All subjects received course credit for their participation.

Procedure. Observers were run individually by one of three different female experimenters. Two of these experimenters each ran 7 observers, and one ran 6 observers in each condition, so that there were 20 observers in each condition. The recruiting folder stated that the study involved gesture learning and that students who were familiar with the manual alphabet for the deaf should not participate.

Observers were assigned to conditions in the order in which they appeared for the experiment. All observers were brought into the subject room and told that this was a study of nonverbal learning. They were asked to learn pairs of gestures that would be presented by means of videotape. It was explained that the videotape showed a subject in a previous experiment. Only one tape was used—the one employed in Experiment 1 showing a female model. The instructions given to all observers were those used in the learning condition in Experiment 1.

The 6 male and 14 female observers assigned to the instructed condition (IC) were given the following additional instruction: "Previous experiments have shown that if you associate words with gestures it will help you learn. So please use this form of verbal coding to help you learn." The remaining 7 male and 13 female noninstructed observers (NC) did not receive this added instruction.

The one-way mirror in the room was completely covered by a fiberboard. The videotape deck was located in the subject's room alongside the small television monitor. The experimenter explained that she would turn on the deck and leave the room so as not to distract the observer during the presentation and

[6] The authors of Experiment 3 were Seymour M. Berger, M. Estela Sanchez, Judith F. Krashmer, and Linda L. Carli.

[7] Two additional subjects were excluded from the data analysis because they did not meet the procedural requirements.

Table 4
Means and Percentages for Self-Reported Mediation: Experiment 3

Condition	Mediator									
	Mimicry		Images		Words		Other		Total	
	M	%	*M*	%	*M*	%	*M*	%	*M*	%
Noninstructed	5.50	100	2.70	55	.40	15	1.65	35	2.56	100
Instructed	4.55	80	2.40	55	3.25	65	1.20	30	2.85	100
Total	5.03	90	2.55	55	1.83	40	1.43	33	2.71	100

Note. There were eight gestures, so each mean could range between 0 and 8.

that she would return after the presentation was over to test the observer's learning of the pairs of gestures. If there were no questions, the experimenter started the videotape and left the room, leaving the door slightly ajar. In this way, she could hear when the presentation ended and return to the room to test the observer.

After the test, in which she recorded each gesture correctly performed, the experimenter asked the observer to complete the questionnaire. The questionnaire was the same as that used in Experiment 2, except that there were no questions about mediation after the television presentation; the appropriate gestures from the manual alphabet were substituted for cultural gestures.

Results

Self-reported mediation. The mixed design ANOVA revealed a significant main effect for mediators, $F(3, 114) = 17.76$, $p < .001$, and a significant Conditions × Mediators interaction, $F(3, 114) = 5.10$, $p < .005$. The means and percentages involved in these comparisons are reported in Table 4.

The Conditions × Mediators interaction indicates that both conditions showed a similar pattern of mediation except with regard to the use of words. As expected, the IC observers used significantly more words than the NC observers. Within both conditions, use of mimicry was greater than use of images or "others," and the difference between the use of images and the use of "others" was not significant. For NC observers the level of imaginal coding was significantly greater than the level of verbal coding; for IC observers the level of verbal coding did not differ significantly from either the level of imaginal or "others" coding. These differences are based on a Bonferroni t test with a familywise error rate set at .10, so that the alpha level was .00 for the 16 specific comparisons.

Observers' learning. Separate ANOVAs for the two learning measures (i.e., numbers of pairs learned and number of gestures learned) did not yield significant differences between conditions. In pair learning, the mean number of pairs learned for NC observers was 1.25; for IC observers it was 1.35. The mean for number of gestures learned was 4.90 for NC and 5.40 for IC observers.

Manipulation checks and suspiciousness. The manipulation checks revealed that the vast majority of observers correctly recalled the instructions they received and that the model had performed the gestures. Only five observers were suspicious about the instructions. Three of these observers were suspicious because they were not given sufficient justification for the learning task, and two were suspicious because the distinction between pairs of gestures in the videotaped presentation was not clear.

Discussion

Given the absence of both imaginal and "other" forms of coding found in Experiment 1 for unfamiliar observers, the occurrence of both of these forms of coding in Experiment 3 among NC observers was unexpected. Since observers in Experiment 3 were told that they were watching a videotape of a previous subject, perhaps the experimenter's selection of this particular subject's performance implied a demand to mimic as well as approval for

the use of coding strategies in general. Another possibility is that observers pay more attention to a "live" model (Experiment 1) and, therefore, are somewhat distracted from considering or engaging in symbolic coding when they have no available symbolic code. Finally, the summer school undergraduates recruited for Experiment 3 may have been more motivated or more skilled in learning strategies than regular-session students; several subjects were somewhat older than traditional college undergraduates. Whether mode of presentation or subject selection accounts for these differences in mediation between Experiments 1 and 3 cannot be determined without further investigation.

General Discussion

Although observational learning was related to symbolic coding (i.e., letters in Experiment 1 and words in Experiment 2) among observers with a salient code for the model's behavior, these observers also engaged in a considerable amount of mimicry and imaginal coding that had no *apparent* relationship to their learning. It is clear from the observers' questionnaire responses that these observers mimicked and imaginally coded because they believed that these forms of mediation would help them learn.

Since these observers had learned to perform the gestures previously, it is not surprising that the additional mimetic practice failed to directly enhance their learning. It is possible that mimicry was an unintentional reaction to the model's performance, because the model performed the gestures in all conditions. This interpretation would account for mimicry but not for imaginal coding.

Perhaps a dual or multiple-stage coding process is involved, similar to the one suggested by Bandura and Jeffery (1973) and Jeffery (1976). For observers with a highly salient and well-learned letter or word code, it may be more efficient for them to store and retrieve the model's behavior in terms of these symbolic codes. Use of mimicry (or other nonverbal codes) may help observers retain, temporarily, those model responses which they are unable to letter- or word-code immediately. Thus, using mimicry (or other nonverbal codes) provides more time for observers to employ their well-learned letter or word codes for these behaviors.

It also is possible that the self-report measures of mediation are not valid indexes of the observers' actual mediational behavior. Although substantial correlations were found in Experiments 1 and 2 between observed and self-reported mimicry, self-reported mimicry was significantly lower than observed mimicry. Furthermore, even observed mimicry tends to underestimate the total amount of relevant motor activity in this type of situation, as revealed by electromyographic recordings (Berger et al., 1970). Nevertheless, even though observed and self-reported mimicry measures probably lack absolute accuracy, these measures are assumed to be reasonably sensitive to relative differences in the observers' mimetic activities. They both show comparable relationships with observational learning in Experiments 1 and 2 (where both measures were obtained). If the self-report measure of mimicry is considered to have some degree of validity, then it is reasonable to assume that self-reports of other forms of mediation have some degree of validity as well.

Finally, two additional points should be noted. The correlations reported in these studies probably are attenuated because of the low variability in the measures of mediation and learning. The test of learning was administered within a few minutes after the observers' exposure to the model. The long-term effects of mediation in learning, which are of considerable interest to observational learning theorists, were not examined in these experiments.

A Step in the Socialization of Altruism as Hedonism: Effects of Negative Mood on Children's Generosity Under Public and Private Conditions

Douglas T. Kenrick
Montana State University

Donald J. Baumann and Robert B. Cialdini
Arizona State University

Prior research has indicated that although negative mood-induction procedures reliably lead to enhanced helping in adults, such procedures do not produce increased helping in young children. Consistent with the negative state relief model, it was expected that, relative to neutral mood subjects, children in a negative mood would be more generous if the helping opportunity offered the potential for direct reward through social approval. This expectation was supported in a pair of studies wherein first- through third-grade children were asked to imagine either neutral or sad experiences and were then given the opportunity to be charitable either in public or in private. Experiment 2 provided evidence that the enhanced public helping of negative mood subjects is more parsimoniously interpreted as an attempt to remove negative mood than to repair public image. Finally, a three-step account of the development of altruism as a self-reward is proposed.

A large number of studies have shown increased helping as a function of experiences that are likely to have induced negative moods in adult subjects (e.g., Aderman & Berkowitz, 1970; Apsler, 1975; Filter & Gross, 1975; Freedman & Doob, 1968; Freedman, Wallington & Bless, 1967; Greenglass, 1969; Kidd & Berkowitz, 1976; Konečni, 1972; Rawlings, 1968; Steele, 1975). Cialdini and his associates (Cialdini, Darby & Vincent, 1973; Cialdini & Kenrick, 1976) have suggested a negative state relief model of altruism to explain these data. According to this notion, altruistic behavior is self-gratifying and will serve to alleviate temporary negative mood states in the same way that any other mood-enhancing experience will. Such a notion is consistent with research demonstrating that negative mood will increase the likelihood of other forms of self-reward (Rosenhan, Underwood, & Moore, 1974; Underwood, Moore, & Rosenhan, 1973) and receives direct support from the study by Cialdini et al. (1973). These authors found that although a negative mood-inducing experience generally led to increased helping, this relationship did not hold for subjects who received a gratifying event (money or praise) between the negative experience and the helping opportunity. Apparently, the negative affective state was cancelled for these subjects by the application of a reinforcer, and it was no longer necessary to employ the helping response for that purpose.

In contrast to the studies showing a general tendency for mood-lowering procedures to lead to increased helping, there is a body of data indicating that such procedures typically lead to some degree of decreased helping (e.g., Isen, Horn, & Rosenhan, 1973,

Studies 1 and 3; Moore, Underwood, & Rosenhan, 1973; Rosenhan et al., 1974; Underwood, Froming, & Moore, 1977). Cialdini and Kenrick (1976) sought to reconcile these seemingly discrepant findings by pointing out that the data showing a direct relationship between lowered mood and helping have come from adult subjects, whereas the data failing to show such a relationship have generally come from work on children. Cialdini and Kenrick reviewed evidence to support the position that altruism acquires its self-reinforcing qualities as a function of the socialization process, wherein helping behavior is systematically paired with various forms of direct reinforcement (e.g., praise, reciprocated aid, thanks, etc.). On the basis of that review, it was expected that young children who had not completed the socialization experience would not find helping behavior gratifying and, hence, would not use it to dispel a negative mood state. However, it was expected that with age, individuals would increasingly employ prosocial activity as a self-gratifier when in a negative mood. In support of these expectations, Cialdini and Kenrick found that the relationship between negative mood and helping progressively changed from an inverse to a direct one over three groups of increasingly older subjects, only the oldest (high school students) of whom showed significantly enhanced helping under negative mood.

Normative Versus Autonomous Altruism

One implication of the negative state relief formulation is that young children will not show enhanced helping while in a negative affective state unless the helping leads to some kind of direct, extrinsic reward (e.g., social approval). Rosenhan (1970) has suggested that altruism can be divided into two categories: normative altruism, based on sanctions associated with social norms, and autonomous altruism, which occurs in the absence of external reward and which must be internalized. However, in the above-cited studies investigating the influence of negative mood on children's helping, only autonomous altruism has been examined, since the opportunity to behave charitably has always been anonymous. In keeping with the negative state relief formulation, we would expect that, were the helping situation to provide the opportunity for normative social reward, negative mood would increase help giving in young children.

There are data to suggest that primary school children are aware of the normative sanctions for helping. For example, Ugurel-Semin (1952) found in 6- to 9-year-old children an increasing recognition of the pressures exerted by norms and customs on the decision to share. Similarly, Eisenberg-Berg (in press) found a substantial tendency for 7- and 9-year-olds to employ social approval reasons as justification for prosocial action. Further, Bryan and Walbek (1970) found that the majority of their 8- to 9-year-old subjects verbally indicated to an adult experimenter knowledge of the social desirability of helping. These authors found, however, that their subjects' verbalizations about the appropriateness of helping did not predict their actual generosity in the absence of the experimenter. Thus, it appears that while young children are aware that social approval is likely to follow their prosocial activity, they have not yet internalized the norms for helping.

The present investigation was designed to test the hypothesis that primary school children should show *increased* helping as a function of negative mood induction in a situation involving normative (or publicly observable) altruism, since the potential for external reinforcement would be present in the form of social approval. In Experiment 1, first- through third-grade children were given either a private or a public opportunity to behave charitably. In the public condition, an adult was present during an opportunity for the child to contribute some rewards to other children. In the private condition, no adult was present during this time. In accord with the negative state relief model, it was expected that negative mood would produce significant increases in the helping behavior of children, as it does for adults, but only in the public condition. That is, negative mood would serve to increase normative altruism, but not autonomous altruism, since children

at this age would not be expected to have yet internalized the reward properties of prosocial behavior.

Experiment 1

Method

Subjects. Subjects were 72 first- through third-grade children (35 males, 37 females) from an elementary school in a middle-class suburban area.

Procedure. The procedure used in the present investigation was identical to that used by Cialdini and Kenrick (1976) with two exceptions: the inclusion of a brief check on the mood manipulation and the introduction of a public helping condition.

Briefly, subjects were brought individually to an experimental room containing a table and chairs, books, a tape recorder, and a box labeled "Coupons for other students." Subjects were told that they would be participating in two separate tasks, an initial "hearing task" and a subsequent "imagination task." They were told that for their participation they would receive several coupons that could be exchanged for a valuable prize at the end of the week. It was stressed that larger accumulations of coupons would result in better prizes. The experimenter directed the subjects' attention to the sealed box and explained that they could donate some of their winnings to the other students who would not get a chance to participate in the experiments.

Subjects then performed a hearing task and were given 10 coupons for their participation. The first experimenter then left, and a second experimenter, always of the same sex as the subject, entered and began the imagination task, which constituted the mood manipulation. Each subject received 5 coupons before the onset of this task.

Mood manipulation. Half the subjects (negative mood) were asked to reminisce about a sad experience, and half were asked to imagine a book and a chair (neutral mood). This was done in a manner identical to that of Cialdini and Kenrick (1976), except that following the mood manipulation, subjects were asked, "Did what you just thought about make you feel better than you usually feel, about the same as you usually feel, or worse than you usually feel?" The sequence in which these possibilities were presented was counterbalanced across subjects. Responses were coded on a 1–3 scale, with 1 indicating the most positive response.

Helping opportunity. After the mood manipulation, the second experimenter left the room, and the first experimenter (blind to the subject's mood condition) returned. In the private condition, the experimenter explained that the tasks were done and (while ostensibly resetting the tape recorder) thanked the subject and said there would be a short delay before the subject would be accompanied back to the classroom. The experimenter again called attention to the box labeled "Coupons for other students," reminded the subject of the option to share coupons, and left the subject alone for 90 sec.

In the public condition, the experimenter performed the same behaviors except that instead of leaving after the reminder, he or she remained in the room and observed the subject's behavior during the 90-sec helping opportunity.

For ethical reasons, the experimenter had all negative mood subjects imagine happy events at the completion of the experiment. A second manipulation-check procedure indicated that the negative mood was removed as a result. Subjects were then asked not to discuss the tests with any of their classmates until the end of the week.

Independent variables. Three factors were varied: mood (negative vs. neutral), type of helping opportunity (public vs. private), and sex of subject.

Dependent variables. Two dependent variables were employed. The subjects' responses to the mood manipulation check constituted one dependent variable. The major dependent variable was the mean number of coupons contributed per cell.

Predictions. It was expected that for our young subjects, helping would be substantially enhanced only when they were in a negative mood and the possibility of external reward existed. Consequently, the negative mood/public condition was predicted to produce more helping than the other three conditions, which were not expected to differ among themselves.

Results

A 2 × 2 × 2 analysis of variance revealed that sex of subject had no effect on either dependent variable; thus the means for both the number of coupons contributed and the mood manipulation check are collapsed over sex and are presented in Table 1.

Manipulation check. The results of the analysis of variance on the mood-check item

Table 1
Mood and Helping Scores for Experiment 1

Measure	Type of helping opportunity			
	Private		Public	
	Neutral mood	Negative mood	Neutral mood	Negative mood
Mood check	1.72	2.06	1.50	2.55
M coupons contributed	1.44	1.22	1.50	3.50

Note. Range is 1–3 on mood check (1 = positive mood, 3 = negative mood) and 1–15 on coupons contributed. *n* per cell = 18.

showed the predicted main effect for the mood induction. Mean values (displayed in Table 1) suggest that negative mood subjects indicated more negative feelings as a result of their ideations, $F(1, 64) = 17.08$, $p < .001$. In addition, there was an unexpected interaction of mood induction with type of helping opportunity, $F(1, 64) = 4.32$, $p < .05$, suggesting that the mood manipulation, although producing a similar effect for both public-condition and private-condition subjects, was somewhat stronger in magnitude for subjects who were subsequently given a public helping opportunity. No other effects were significant for this variable.

Coupon sharing behavior. Since the prediction was made that the largest number of coupons would be contributed during a public helping opportunity following a negative mood induction, an a priori contrast (Hays, 1963, p. 466) was performed to test this prediction. This contrast pitted the public negative mood group against the mean of all other groups. In addition, the residual between-groups variance was tested to determine whether any remaining effects due to the independent variables existed. It was expected that the between-groups variance for the a priori contrast would account for the majority of the variance.

Results indicated that the prediction was borne out. Subjects in the negative mood/public condition contributed substantially more coupons than did subjects in the other cells (means are displayed in Table 1). The a priori contrast indicated that this effect was significant, $F(1, 68) = 9.55$, $p < .003$. In addition, this contrast accounted for 99% of the between-groups variance, whereas the remaining comparisons testing all other orthogonal effects were nonsignificant ($F < 1$) and accounted for only 1% of the variance.

Discussion

As expected, subjects who were exposed to negative mood-inducing operations and who had the opportunity to help in the presence of an experimenter donated the most coupons. Negative mood subjects whose opportunity to help occurred in private, however, were not especially likely to share their coupons. In fact, they were slightly less generous as a result of the negative induction procedure, a result that is consistent with the prior literature involving anonymous giving in young children. It appears, then, that negative mood did not lead to increased helping in our young subjects unless the helping opportunity offered the likelihood of direct social reward for generosity. It is our argument that helping will be employed by individuals in a lowered mood state in order to relieve their negative affective state. For adults, who have internalized the reward value of benevolence, the help may occur in private and still retain its self-gratifying function. For young children, on the other hand, altruism has not yet become autonomous and, thus, will be gratifying only when it is instrumental to an extrinsic form of reward like public approval.

Negative mood relief or image repair. The finding that our young subjects were more likely to help when in a negative mood and in public is compatible with some earlier results by Isen et al. (1973). They found (Experiments 2 and 3) that a public failure had a positive effect on young children's charitable donations made in the presence of an experimenter who knew of the failure. The authors accounted for the finding with an image repair explanation: The visible failing produced a lowered public image that subjects then sought to repair via prosocial action. Our own interpretation of those data would be somewhat different: The public failure produced a lowered mood that subjects then sought to remove via prosocial action. Setting aside the question of how to best interpret the Isen et al. results, the image repair notion of those authors presents a potential alternative explanation for the data of the present study. Perhaps, in asking negative mood subjects to reminisce aloud about a sad experience, we caused a large percentage of them to divulge image-damaging things about themselves. If so, the enhanced coupon donating that occurred in the negative mood/public condition may have been a result of attempts to raise a lowered public image rather than to relieve a negative mood.

To test the negative state relief versus im-

age repair interpretations of our findings, a second experiment designed to replicate and extend the results of Experiment 1 was conducted. A test of these alternative formulations gains importance because the image repair interpretation could account for many of the studies showing that certain negative mood procedures resulted in greater helping among adult subjects. Although Cialdini and Kenrick (1976) interpreted such results according to the negative state relief model, increased aid following a public transgression (e.g., Konečni, 1972), receipt of an insult (Steele, 1975), receipt of a deviant score on a personality test (Filter & Gross, 1975), or public embarrassment (Apsler, 1975) could conceivably have occurred in an attempt to restore public image.

A second reason for performing a replication of Experiment 1 involved the unexpected interaction that appeared on our mood manipulation check in that study. Even though the means in Table 1 suggest that the mood induction procedure was successful for subjects who were subsequently randomly assigned to both public and private helping opportunity conditions, the induction appears to have been stronger among those in the public cells. While the pattern of means makes it unlikely that this factor mediated our results, it was felt that confidence in the results of Experiment 1 would be enhanced by a replication showing equivalently strong negative mood induction among public and private condition subjects. To these ends, a replication of Experiment 1 was conducted that included an additional manipulated variable—whether the negative mood-induction procedure required subjects to imagine negative experiences that were image related or image unrelated.

Experiment 2

Method

Subjects. Subjects were 77 first- through third-grade children (42 males, 35 females) from an elementary school in a middle-class suburban area. This was not the same school used in Experiment 1.

Procedure. The procedure was identical to that used in Experiment 1 with the exception that subjects in the negative mood cells were divided into an image and a nonimage condition. These conditions were operationalized in the following way: Experiences spontaneously generated by subjects in Experiment 1 were divided into image and nonimage categories by two independent raters. There was 90% agreement between raters. The four most frequently occurring responses in each category had 100% agreement between raters and were selected for experimental conditions.[1]

Negative mood was manipulated by asking one half of the subjects if they had ever experienced the most frequently occurring non-image-related response, whereas the other half were asked the same question about the most frequently occurring image-related response. If subjects responded "yes" to this first probe, the experimenter proceeded to induce a negative mood state in a manner identical to Experiment 1. If subjects responded "no," the experimenter continued down the list of image or nonimage experiences until an affirmative response was generated. None of the subjects responded "no" to all four probes.

Predictions. It was expected that helping would again be greatest in the negative mood/public condition and that this effect would not vary as a function of the image manipulation.

Results

A $3 \times 2 \times 2$ analysis of variance again revealed that sex of subject had no effect on either dependent variable; thus, the means for these measures were collapsed over sex and can be found in Table 2.

Manipulation check. Once again, the manipulation check showed a significant main effect of the mood manipulation, $F(2, 65) = 20.68$, $p < .001$. In this experiment, neither the type of helping opportunity nor the interaction with mood induction was significant for this variable (both $Fs < 1$). No other effects approached significance.

Coupon sharing behavior. The initial $3 \times 2 \times 2$ analysis of variance also revealed that no significant differences occurred as a function of the image manipulation (all $Fs < 1$). Examination of the means in Table 2 indi-

[1] The nonimage condition contained the following experiences: (a) Have you ever had a pet you owned die? (b) Have you ever had a toy you liked broken, lost, or stolen? (c) Have you ever been hurt in an accident? (d) Have you ever had someone you like very much move away? The image condition included (a) Have you ever been called a bad name? (b) Have you ever been caught doing something wrong? (c) Have you ever been punished for doing something wrong? (d) Have you ever been left out of a game you wanted to be in?

Table 2
Mood and Helping Scores for Experiment 2

Measure	Type of helping opportunity: Private — Neutral mood (n = 13)	Private — Negative mood: Nonimage (n = 12)	Private — Negative mood: Image (n = 11)	Public — Neutral mood (n = 14)	Public — Negative mood: Nonimage (n = 13)	Public — Negative mood: Image (n = 14)
Mood check	1.92	2.66	2.72	1.68	2.69	2.78
M coupons contributed	1.39	2.00	1.00	2.07	3.15	2.93

Note. Range is 1–3 on mood check (1 = positive mood, 3 = negative mood) and 1–15 on coupons contributed.

cates that if anything, image-related negative mood led to relatively less helping than nonimage-related negative mood.

Since there was no difference between the image and the nonimage cells, the means for the major dependent measure were collapsed over type of negative mood induction, and the negative mood/public group was pitted against all other groups, as in Experiment 1. Once again, results indicated the most helping by subjects in the negative mood/public cell (see Table 2).[2] The a priori contrast for this effect was significant, $F(1, 73) = 3.05$, $p < .05$, one-tailed test. Further examination of these results indicated that this contrast accounted for 90% of the between-groups variance, whereas the remaining orthogonal comparisons were nonsignificant ($F < 1$) and accounted for 10% of the variance.

Rosenthal (1978) has recently reviewed a number of methods for combining the results of independent studies, suggesting that the most serviceable technique among those available is the method of adding Z scores (Mosteller & Bush, 1954). When looked at in this manner, the combined results of Experiments 1 and 2 strongly support the hypothesis that the greatest coupon sharing would occur in the negative mood/public condition, $Z = 2.96$, $p < .003$.

General Discussion

Taken together, the results of both experiments provided clear support for our major hypothesis. While primary-grade children in a situation requiring autonomous (i.e., internalized) altruism did not show the adult pattern of increased helping in a negative mood, the pattern shown in the public condition indicated that *normative* (i.e., sanction-based) helping was increased by negative mood. This latter outcome fits well with the findings indicating increased helping in adults (e.g., Apsler, 1975; Cialdini et al., 1973; Freedman et al., 1967) as well as increased direct self-reinforcement in children (Rosenhan et al., 1974; Underwood et al., 1973) as a function of negative mood induction. Our results are also consistent with the Isen et al. (1973, Study 3) finding that an image-damaging incident will lead to an increase in helping, although the present results do not seem to be explained via the image repair model.

It should be noted that the negative state relief model and the image repair model are in no way incompatible. In fact, damage to image is doubtless one common and potent form of negative state induction. It is our position, however, that image repair seems subsumed under the more general negative state relief model. Image damage is, thus, sufficient but not necessary to lead to increases in normative helping. Other negative experi-

[2] As the means in Table 2 also indicate, an analysis of variance revealed a trend toward a main effect for type of helping opportunity, $F(1, 65) = 2.42$, $p < .12$, with public opportunity to help producing somewhat more aid. A similar trend was found in Experiment 1, $F(1, 64) = 3.72$, $p < .058$.

ences will have the same result. Further, research by Cialdini et al. (1973) has indicated that relief of a negative mood state abolishes the negative-mood-leads-to-helping relationship even when such relief is in no way related to image improvement.

Qualifications on the Negative State Relief Model

A further point of clarification regarding the negative state relief model should be made here. The model suggests that one helps when one is experiencing a transitory feeling of sadness or depression, in order to feel better. As indicated in previous statements of the model, (Cialdini et al., 1973; Cialdini & Kenrick, 1976) negative experiences likely to arouse feelings of frustration or anger would not be expected to result in altruistic behavior. Additionally, if the helping is effortful or unlikely to yield great benefit, negative mood might be expected to reduce helping even in adults. This latter suggestion is supported in a recent article by Weyant (1978). He found that a negative mood induction increased helping in his subjects, but only when the cost of helping was low and the potential benefits were high. Conversely, when cost of helping was high but potential benefits were low, helping was somewhat decreased by negative mood.

There is also recent evidence that negative mood can sometimes reduce helping by producing an attentional deficit. McMillen, Sanders, and Solomon (1977) found that negative mood subjects were less attentive to their environment than neutral mood subjects and, consistently, were less helpful to a female confederate in distress, unless she drew attention to herself. In the latter condition, negative mood produced greater helping than either neutral or positive mood conditions.[3] The tendency to engage in altruistic behavior as a means of self-reward following negative state induction, then, seems to be mediated by the reward value and the salience of the helping opportunity. In keeping with the hedonistic basis of the model, it appears that if a helping opportunity is not perceived as likely to lead to a better mood, negative mood will not enhance helping. These findings are consistent with the notion that helping will occur in a negative mood in order to alleviate such aversive feelings.[4]

It was interesting that whereas means for helping in the public conditions were invariably higher than those in the relevant private comparison, the public–private effect was not more pronounced in the neutral mood conditions. It would seem that the children generally judged the value of the unknown prize to be potentially more valuable than the immediate social approval of the experimenter, but that negative mood enhanced the importance of such immediate approval.

The Socialization of Altruism as a Self-Reinforcer: A Three-Step Model

It will be recalled that the Cialdini and Kenrick (1976) data indicate that the relationship between helping and negative mood changes from an inverse to a direct one as an individual passes through the socialization process. When those data are taken in combination with the results of the present investigations, a three-step model of the socialization of altruism as a self-reward emerges. Initially, helpful behavior would be rarely performed by an unsocialized individual, since it involves the loss of rewards. There is substantial evidence that preschool-age children help infrequently and that when they do help, it is unrelated to social approval (Eisenberg-Berg & Hand, in press; Fischer, 1963; Ugurel-Semin, 1952). At this step,

---

[3] Another recent study, by Underwood, Berenson, et al. (1977), failed to find increased helping in negative mood subjects as a function of an attention manipulation, and these authors' suggestions may be compatible with Weyant's (1978) more recent findings. They propose that negative mood subjects may simply not have perceived a great need of help. Unfortunately, since mood induction was accomplished by using subjects who were leaving movie theaters and had observed very different films, it is possible that a number of uncontrolled factors may have been operative in this study. Further research is needed to clarify the contradiction between the Underwood, Berenson, et al. (1977) and McMillen et al. (1977) studies.

[4] We are indebted to Robert A. Baron for his contributions regarding the thinking contained in this paragraph.

helpfulness would be unlikely under conditions of negative mood, since it would be experienced as self-punishment.

The second step involves children's acquisition of the norms for prosocial behavior, without concomitant internalization of these norms. Children at this step, usually in the primary grades, are aware that helping can lead to systematic social reinforcement (Bryan & Walbek, 1970; Eisenberg-Berg, in press; Ugurel-Semin, 1952) and employ a public helping opportunity to obtain external social reward when in a negative mood, as suggested by the data of the present studies. However, such children may still tend to be less helpful under negative mood when the helpfulness is anonymous (Cialdini & Kenrick, 1976; Moore et al., 1973; Rosenhan et al., 1974; Underwood, Froming, & Moore, 1977).

Finally, after sufficient experience with external reward for charitable action, that behavior itself takes on the quality of a secondary reinforcer (Weiss, Buchanan, Alstatt, & Lombardo, 1971). Weiss et al. found that for college students, the opportunity to behave altruistically acted as a reinforcer in a learning task and concluded that altruism itself was rewarding for their subjects. A study by Pisarowicz (Note 1) has provided additional support for the notion that altruism is self-rewarding for adults. Subjects in Pisarowicz's study indicated a greater sense of self-satisfaction and a lessened tendency to engage in direct self-gratification (prize tokens) following altruistic behavior. Consistently, charitable behavior in adults occurs with enhanced frequency under conditions of negative affect (see Cialdini & Kenrick, 1976, for a review), presumably to dispel the bad mood. For the individual who has reached this level of socialization, usually by high school age, helpfulness will have become self-gratifying and will frequently occur privately without the expectation of material or social reward.

The Organizational Functions of the Self: An Alternative to the Duval and Wicklund Model of Self-Awareness

Jay G. Hull and Alan S. Levy
Duke University

A model is proposed that defines the essential functions of self-awareness in terms of the cognitive organization or encoding of information according to its self-relevance. This view is contrasted with a definition of self-awareness in terms of self-focused attention, self-evaluation, and motivated affect reduction. Three experiments are presented in support of the proposed encoding model. The first experiment uses an incidental memory paradigm to demonstrate that self-awareness is associated with a particular encoding depth. The remaining two experiments use previous self-awareness paradigms to demonstrate that self-criticism and self-attribution are not characteristic of self-awareness per se, but rather depend on aspects of the immediate situation. On the basis of this evidence, it is suggested that self-awareness phenomena are a function of a particular form of informational encoding rather than the attentional activation of a self-evaluative process.

The importance of an adequate theory of self for any complete account of human social behavior has long been recognized by philosophers and psychologists alike (Freud, 1927; James, 1890/1950; Kant, 1780/1958; Lewin, 1935; Mead, 1934). These theorists have for the most part distinguished two functions of self: that of organizing the individual's understanding of the social environment and that of regulating behavior through a process of self-evaluation. It is this latter regulatory aspect of the self that has been emphasized in modern social psychology (Bem, 1972; Festinger, 1957; Nisbett & Valins, 1971). According to this view, behavior follows from an evaluation of past activities and as such represents a conscious attempt at self-regulation. While not denying that self-evaluation can serve to mediate behavior in this way, we feel that these theories have tended to restrict unnecessarily the role of the self to a process of self-concept regulation while essentially ignoring its broader function of organizing the individual's understanding of the social environment. This is most easily seen in a recent theory of objective self-awareness (Duval & Wicklund, 1972; Wicklund, 1975).

In terms of the Duval and Wicklund model, self-awareness [1] is composed of four discrete stages: self-focused attention → self-evaluation → affective reaction → motivated discrepancy reduction. Very briefly, attention can be focused in one of two directions: inward on the self or outward on the external environment. Self-focused attention is hypothesized to induce an evaluation of the present self in terms of the individual's ideal self-

The authors especially wish to thank Bruce Saltz for his assistance in Experiment 1 and Steven G. West, Charles Bond, and Timothy D. Wilson for their advice and criticism of earlier drafts of this article.

Requests for reprints should be sent to Jay G. Hull, Department of Psychology, Duke University, Durham, North Carolina 27706.

[1] Duval and Wicklund (1972) originally defined self-awareness in terms of the ratio of an objective (self-focused) to a subjective (environment focused) state. In contrasting their theory with others, then, high self-awareness was postulated to correspond to higher levels of objective as opposed to subjective self-awareness. Following the lead of others, we have substituted the term "self-awareness" for the more cumbersome "objective self-awareness" in connection with their position throughout the present article.

image. Recognition of a real–ideal discrepancy is hypothesized to elicit an affective reaction —positive or negative depending on the direction of the discrepancy. Upon recognizing that one's ideals exceed one's present self and experiencing a negative reaction, the individual is postulated to be motivated to reduce the degree of negative affect by either (a) working to reduce the size of the real–ideal discrepancy or (b) avoiding the self-aware state. The Duval and Wicklund (1972) theory thus explicitly defines the relation between self and behavior in terms of a regulatory process of self-evaluation and in addition specifies a boundary condition on this process in terms of self-focused attention.

An Encoding Theory of Self-Awareness

In contrast to Duval and Wicklund (1972), we would propose that the defining features of self-awareness do not exist in terms of self-focused attention and the operation of a particular kind of self-evaluative process, but rather exist in terms of the individual's organization of the social environment prior to focal attention and comparison processes. Specifically, we propose that self-awareness corresponds to the encoding of information in terms of its relevance for the self and as such directly entails a greater responsivity to the self-relevant aspects of the environment. Situationally, this level of encoding may be a consequence of the nature of the assigned task, the specific instructions, or the presence of self-symbolic cues (e.g. mirrors, videotape and audiotape recordings). Dispositionally it may represent either a general propensity on the part of the individual or a by-product of more elaborate cognitive structures corresponding to relationships between the self and the environment (Markus, 1977; Rogers, Kuiper, & Kirker, 1977).

The present distinction between encoding and focal attention/comparison processes is common to several recent theories of cognition (Neisser, 1967; Shiffrin & Schneider, 1977; Sternberg, 1975). In terms of a model proposed by Shiffrin and Schneider, feature encoding corresponds to the automatic activation of specific cognitive structures in response to a particular input configuration and as such operates through a set of associative connections in long-term memory. On the other hand, controlled processing corresponds to a capacity-limited comparison or search process dependent on focused attention and under the control of the individual. Since feature encoding defines the form of information available to the individual, it need not be associated with different kinds of controlled processes to lead to different behavioral effects. Thus, encoding may be associated with automatic responses that do not require controlled processing, or, by its inherently constructive nature, encoding may determine the outcomes of those controlled processes that do occur.

From our own perspective, then, self-awareness corresponds to a particular form of encoding process that has its effects on behavior independent of focal attention and comparison processes by rendering the individual sensitive to those aspects of the environment that are potentially self-relevant. It follows from such an analysis that before one can define the behavioral effects of self-awareness, one must specify the ways in which particular aspects of the situation are relevant for the self. We propose that information about one's present situational context is principally self-relevant insofar as it specifies contingencies related to the individual's present activities or projects (Mead, 1934). As such, self-awareness will serve to increase the individual's understanding of the immediate situation in terms of contingencies bearing on those activities. To the extent that such self-relevant contingencies are defined by the responses of others, self-awareness prior to behavior will lead to actions consistent with situational definitions of appropriate conduct (e.g., Carver, 1974, 1975; Diener & Wallbom, 1976; Duval, 1976; Liebling & Shaver, 1973; Scheier, Fenigstein, & Buss, 1974; Wicklund & Duval, 1971). While self-awareness will thus be associated with greater responsivity to situational variations in self-relevant contingencies, it will also be associated with behavioral consistency across situations involving activities that define similar self-relevant contingencies (e.g., Pryor, Gibbons, Wicklund, Fazio, & Hood, 1977).

In addition, we propose that information about past performances and present physiological states also constitutes self-relevant information insofar as it specifies particular kinds of relationships between self and environment. Self-awareness as a greater sensitivity to such information will be associated with a greater responsivity to the evaluative and affective connotations of the information (e.g., Gibbons & Wicklund, 1976; Steenbarger & Aderman, in press; Scheier & Carver, 1977; Gibbons, Note 1). The claim, however, that self-awareness involves a naturally self-evaluative and affect-inducing state (Duval & Wicklund, 1972; Wicklund, 1975) is simply unsubstantiated in the literature to date.

In terms of research issues, our alternative raises questions about three separate aspects of self-awareness theory: (a) To what extent is a state of self-awareness based on a state of self-focused attention? (b) To what extent are the behavioral effects of self-awareness mediated by processes of self-evaluation and affect reduction? (c) To what extent are the attributional effects of self-awareness based on attentional differences? Previous research bearing on each of these issues will be briefly considered along with three studies specifically designed to illustrate our own perspective.

Focal Attention or Encoding Processes?

Two of the main tests of the focus of attention hypothesis have used projective measures (Carver & Scheier, 1978; Davis & Brock, 1975). While these studies did indeed find that self-awareness manipulations led to increases in self-referent responses, we would contend that this was not because of an autistic self-focus, but rather reflects a general propensity to construct the environment in terms of its relationship to the self. In contrast to such projective techniques, Geller and Shaver (1976) have recently used the Stroop color-word test (1938) to demonstrate basic processing differences among differentially self-aware subjects. Thus, self-aware subjects were found to be more sensitive to irrelevant aspects of a color-naming task when those aspects involved self-relevant as opposed to self-irrelevant information. Non-self-aware subjects were not responsive to this difference. It should be noted, however, that self-aware subjects did not show the *general* decrement in processing speed that should be expected with an attentional focus away from the task (Gopher & Kahneman, 1971; Shiffrin & Schneider, 1977). We would propose that the lack of such an overall processing decrement suggests that self-awareness does not correspond to an attentional focus on the self and away from the environment, but rather corresponds to a particular form of informational encoding that is cued by the presence of self-symbolic stimuli.

To provide support for the notion of self-awareness as an encoding process, the present authors designed an experiment to examine differences in self-relevant encoding among individuals varying in degrees of dispositional self-awareness. It was predicted that individuals with high scores on a measure of private self-consciousness (see Fenigstein, Scheier, & Buss, 1975) would be more likely to encode self-relevant information at a deeper level than (a) information encoded on other dimensions and (b) all information (including self-relevant) processed by individuals low in self-consciousness. The primary dependent measure of encoding depth involved incidental recall following a word evaluation task (Craik & Tulving, 1975; Rogers et al., 1977). The encoding dimensions of word length and meaningfulness were selected as control baselines for comparisons with the encoding dimension of self-relevance. The present design thus varied three levels of encoding dimensions along with two levels of self-consciousness.

Experiment 1

Method

Subjects

Subjects were 66 undergraduates of Duke University who participated in partial fulfillment of a course requirement. All subjects had participated in a group testing session 2 months earlier, during which the Fenigstein et al. (1975) self-consciousness inventory was administered.

Procedure

Subjects were run in small groups varying in size from 4 to 11 people. The procedure consisted of the

following instructions read verbatim:

> In this experiment you will be asked to evaluate a series of 30 words which will be presented one at a time. Each word is to be evaluated on one specific dimension. These dimensions are listed in order on the rating sheets you have been provided.
>
> I will call out a number and you are then to read the statement associated with that number. I will then call out a single word. You are then to place a check in the appropriate column to designate whether or not the statement is applicable to that word: in the left column if yes; in the right if no. Some of the statements ask for an evaluation of the length of the word. For these statements check the left if the word is long, the right if short.
>
> Each word is to be evaluated only with respect to the single statement associated with the word called out. Are there any questions about this procedure?

As long as there were no questions, the experimenter continued by calling out a series of 30 words. In each instance he would first read aloud the number associated with the word, wait 5 sec, read aloud the word itself, and then wait 18 sec before calling out the next number.

Evaluation statements. Each word was to be evaluated with respect to one of the three statements used by Rogers et al. (1977, Experiment 2). The specific criteria used in the present study were (a) how long or short the word was; (b) whether the word was meaningful to the subject; and (c) whether the word described the subject. The first criterion is hypothesized to require the shallowest level of processing; the last, the deepest. The order in which the statements appeared was counterbalanced such that in every three trials, each statement appeared once. Subjects were randomly assigned one of three rating sheets, each of which contained a different order of evaluation statements. Thus, within a testing session a given stimulus word was evaluated with respect to all three dimensions, the specific dimension depending on which sheet the subject had been randomly assigned.

Dependent measures. After evaluating all 30 words, subjects were instructed to turn over their rating sheets and write down as many of the words as they could remember. Since stimuli had been presented verbally, they were available only in memory. Subjects were informed that they would have 3 min to complete the task. At the end of 3 min, subjects were asked to place their names at the top of the rating sheets and return them to the experimenter. The purpose of the experiment was then explained, and subjects were asked not to discuss the nature of the experiment with others.

Results and Discussion [2]

Of the randomly assigned evaluation orders, there were 24 subjects in Order 1, 21 in Order 2, and 21 in Order 3. Within each order, subjects were divided into high and low self-conscious groups by means of a median split performed on private self-consciousness scores (Fenigstein et al., 1975). Two subjects were randomly discarded in order to equalize the number of high and low self-conscious subjects in each evaluation order.

The data were submitted to a mixed-design analysis of variance with the number of words remembered within each evaluation category used as a repeated measure. The main effect of self-consciousness was marginally significant, $F(1, 62) = 3.03$, $p < .10$. The within-subjects analysis consisted of three planned comparisons. As predicted, high self-conscious subjects recalled more words encoded as self-relevant than did low self-conscious subjects, $F(1, 124) = 5.61$, $p < .025$. In addition, high self-conscious subjects recalled more words encoded according to their self-relevance than words encoded according to the other control dimensions, $F(1, 124) = 3.88$, $p = .05$. Finally, low self-conscious subjects recalled nonsignificantly fewer words encoded according to their self-relevance than words encoded according to other dimensions, $F(1, 124) = .11$, *ns*.[3] A comparison testing the interaction of self-consciousness and self-relevant versus control words did not achieve a conventional level of significance, $F(1, 124) = 2.58$, $p = .13$.

---

[2] This experiment was originally run as two separate experiments, the second being an exact replication of the first. The results of each were consistent with our hypotheses, and there were no independent effects associated with "experimental session" when this was included as a factor in the design. Therefore, for the sake of brevity, the results are reported collapsed across experiments.

[3] Six of the 10 items from the private self-consciousness scale were significantly correlated with incidental memory of self-referenced words ($.21 < r < .31$, $p < .05$, one-tailed). Two of the items ("I sometimes have the feeling that I'm off somewhere watching myself" and "I'm aware of the way my mind works when I work through a problem") failed to predict in either experimental session: Session 1 ($n = 20$), $rs = -.08$ and .02, respectively; Session 2 ($n = 44$), $rs = .09$ and $-.06$, respectively. While we feel that these items are more closely associated with a focal attention interpretation of self-awareness than are the remaining items, this distinction is obviously a personal judgment on our part.

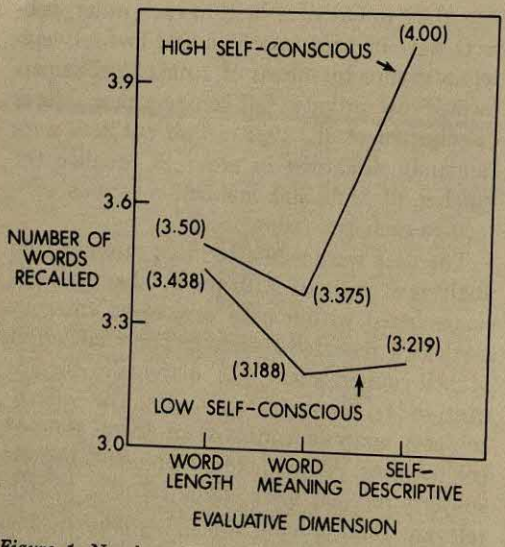

Figure 1. Number of words remembered as a function of self-consciousness and encoding task: Experiment 1.

As can be seen in Figure 1, the pattern of results conformed nicely with predictions. For individuals high in self-consciousness, there is a striking difference between the number of words remembered when encoded as self-relevant as opposed to alternative dimensions. On the other hand, for individuals low in self-consciousness there is no distinction among the different forms of information. This finding occurred in spite of the fact that low self-conscious individuals rated nonsignificantly more of the words as self-descriptive, $t(63) = 1.32$, $p < .20$—a condition that has been found to aid memory on the present task (Rogers et al., 1977).

To determine the effects of the alternative subscales of the self-consciousness inventory, all analyses were repeated using the public self-consciousness and social anxiety indexes as criteria for within-treatment median splits. There were no significant effects for either scale.

The results of the present experiment thus indicate that instructions to self-reference information induce superior incidental recall only for individuals previously identified as dispositionally self-aware. In terms of the analysis provided by Rogers et al., (1977), this would seem to indicate that high self-conscious subjects either (a) possess a more uniform and well-structured cognitive organization corresponding to the self, or (b) this superordinate framework is more easily activated by environmental cues to self-reference. Finally, it should be noted that although self-consciousness was associated with an increased sensitivity to self-relevant information, there was no concomitant decrease in encoding efficiency of non-self-relevant information. We would suggest that these findings, along with those of Geller and Shaver (1976), indicate that self-awareness does not correspond to a bidirectional attentional phenomenon, but rather corresponds to an organizational phenomenon associated with a greater sensitivity to specific forms of environmental information.

Self-Awareness and Self-Evaluation

In addition to denying that self-awareness corresponds to a state of self-focused attention, our analysis is in basic disagreement with the Duval and Wicklund account of the self-evaluative consequences of self-awareness in the absence of performance feedback. The primary evidence for their position exists in the form of an experiment by Ickes, Wicklund, and Ferris (1973) in which self-aware subjects described themselves less favorably relative to their ideals on a "real–ideal self questionnaire." Proponents of the theory claim this study as evidence that under natural conditions, self-aware subjects tend to exaggerate the size of discrepancies between their real and ideal selves. Indirect evidence on subjects whose self-esteem has not been manipulated, however, suggests that self-awareness is associated neither with self-criticism (Carver & Scheier, 1978) nor with the avoidance of generally self-referent responses (Davis & Brock, 1975).

According to our own analysis, a mediational process of self-evaluation and affect reduction is not necessary in order to account for the behavioral consequences of self-awareness. Self-awareness as an encoding process is hypothesized to directly mediate behavioral responses by prefiguring the important and relevant aspects of social situations without engaging a self-evaluative or affect-reduction

process. According to this analysis, subjects' self-critical responses in the experiment by Ickes et al. (1973) were not an inevitable consequence of self-awareness, but rather a consequence of the particular characteristics of the situational context within which the response occurred. It seems likely, for example, that self-deprecation exists as a common self-presentational response to situations similar to that used by Ickes et al. (1973). Lefebvre (Note 2) has shown that female subjects adopt self-deprecation as an ingratiation tactic in the presence of other females and self-enhancement in the presence of males. Self-deprecation in the Ickes et al. study occurred within just such a female (subject) – female (experimenter) interaction. If self-awareness is postulated to heighten the individual's sensitivity to self-relevant aspects of the immediate situation, it might be expected to increase self-deprecation in just this kind of situation.

Although both analyses can explain the results of this particular experiment, they clearly predict different consequences when other variables are introduced. In terms of our analysis, self-deprecation is a response to the immediate circumstances surrounding the self-description. Altering those circumstances by manipulating the characteristics of the audience (e.g., through use of a male rather than a female experimenter) or by rendering the self-descriptions anonymous would be expected to alter the quality of the self-aware response. From the perspective of the Duval and Wicklund (1972) model, such manipulations would not be expected to affect the self-evaluative consequences of self-awareness.

An experiment was designed to test these competing analyses. In accord with our own analysis, it was predicted that self-awareness would lead to self-deprecation when responses were made publicly available to a female experimenter, but the reverse would be true in the presence of a male. In addition, anonymity (by eliminating the self-presentational character of the situation) was predicted to eliminate both of these effects by rendering the sex of the experimenter irrelevant to the subject's behavior. Finally, self-awareness was not predicted to affect subjects' mood. In contrast, Duval and Wicklund (1972) would predict that self-awareness should lead to self-deprecation regardless of other situational variations and that negative affect should be a consequence of this negative self-evaluation.

Experiment 2

Method

Subjects

The subjects were 101 female undergraduates from Duke University who participated in partial fulfillment of a course requirement. Subjects were intentionally restricted to females in order to replicate the conditions of the Ickes et al. (1973) and Lefebvre (Note 2) experiments. Subjects were run individually and randomly assigned to one of eight experimental conditions. Five of these subjects were discarded according to predetermined criteria.[4] The remaining subjects were evenly distributed across conditions.

Procedure

Upon entering the experimental room, subjects were seated before a large (48-inch × 32-inch, 122-cm × 81-cm) mirror that was turned so that its reflective front (high self-aware conditions) or non-reflective back (low self-aware conditions) faced the subject. Subjects' self-descriptions were then obtained under the guise of an experiment described as investigating sex differences in aesthetic reactions. Each subject was shown a stack of art reproductions, along with a series of rating forms for each painting. It was explained that personality and mood differences had to be statistically controlled and that prior to reacting to the pictures it would be necessary for the subjects to fill out two brief self-descriptive questionnaires.

Public and private conditions. Subjects assigned to public conditions were told to write their names and social security numbers on the booklets and to hand them to the experimenter after completing them. In addition, they were told that the booklets would be scored while they rated the pictures, and feedback would be supplied at the end of the experiment.

Subjects randomly assigned to the private conditions were told not to write their names or social

[4] It was determined in advance to discard any subjects in the public conditions who did not put their name on the booklet (two individuals did not) and any subjects in the private conditions who did not place their booklet in the anonymous pile (three individuals did not). The results of all tests of significance are unchanged when these subjects are included in the analysis.

Table 1
Impact of Self-Awareness on Task-Related Self-Descriptions: Experiment 2

Self-awareness	Female experimenter		Male experimenter	
	Public	Private	Public	Private
High				
M	12.67	14.07	14.22	14.11
SD	1.42	1.74	2.01	1.91
Low				
M	15.04	13.11	13.11	14.26
SD	2.03	2.38	1.85	1.18

Note. Higher numbers refer to more positive self-descriptions on a 20-point scale; all statistics are based on 12 subjects per cell.

security numbers on the booklets and after completing them to place them somewhere in the middle of a pile of booklets behind them. No mention was made of the possibility of feedback.

Target other. The characteristics of the individual who would have access to subjects' self-descriptions was varied by using both a female and a male experimenter. For one half of the subjects, the study was conducted by a male experimenter; for the remaining half the experimenter was female.

All subjects were instructed to summon the experimenter after completing the questionnaire. The subject was finally asked if she had any questions about the procedure. As long as there were no questions, the experimenter concluded by commenting that he/she had to share the room with another experimenter and that the bulk of the equipment in the room belonged to the other experimenter's study. The subject was asked not to disturb any of these things, as the experimenter casually indicated the mirror, a tape recorder, and various other experimental stimuli. The subject was then left to work on her own.

Dependent measures. The first questionnaire consisted of a 15-item trait listing. Subjects were instructed to circle numbers from 1 to 10 to indicate the degree of each trait they perceived in themselves. These traits were divided on an a priori basis into three dimensions: task-relevant evaluative (sensitive, creative, unskilled, analytic, and impressionable); general evaluative (careful, intelligent, honest, disagreeable, and crude); and sex-related (masculine, ambitious, forgiving, cooperative, and jealous).[5]

The second questionnaire consisted of a 10-item mood checklist. Once again subjects were instructed to circle numbers from 1 to 10 to indicate the degree of each state they perceived in themselves. These moods were also divided into three dimensions: positive (pleased, positive, pleasant, and lively); negative (depressed, anxious, downhearted, and clutched up); and defiant (defiant, rebellious).

After completion of these questionnaires and the return of the experimenter, subjects were informed that the experiment was over and were probed for suspicion. The actual nature of the experiment was explained to them, and they were thanked for their participation. All subjects were asked not to discuss the experiment with other potential participants.

Results

For the purposes of analysis, the data were combined into the personality and mood categories described above. They were then submitted to a 2 (self-aware vs. non-self-aware) × 2 (public vs. private) × 2 (female vs. male experimenter) analysis of variance.[6]

Personality Self-Descriptions

Task-relevant evaluations. Subjects' responses to these five items were combined by subtracting negative (unskilled) from positive (analytic, sensitive, creative, and impressionable) self-evaluations. The means for each of these eight conditions are reported in Table 1. An analysis of variance on these combined scores revealed a significant triple interaction, $F(1, 88) = 9.27$, $p < .005$. There were no other significant effects. Post hoc analyses indicated that differences in public conditions were primarily responsible for this interaction. Thus, the two-way interaction of self-awareness and sex of experimenter was significant in public (Scheffé procedure, $p <$

[5] The first three task-relevant evaluative and the first four general evaluative traits appeared in the original Ickes et al. (1973) study. An analysis of these seven traits revealed effects identical to the task-relevant and general evaluative dimensions reported below. The two remaining task-relevant traits were regarded as positive skills in the immediate situation of judging art reproductions.

[6] If the distinction is not made between general evaluative, task-relevant, and sex-related traits, and items are combined only on the basis of their positive–negative qualities, the results remain basically the same. Thus, both the triple interaction, $F(1, 88) = 14.92$, $p < .001$, and the sex of experimenter main effect, $F(1, 88) = 3.82$, $p < .06$, are significant. As can be seen in the more extensive analysis, however, the former effect is restricted to general evaluative and task-relevant self-descriptions, whereas the latter only appears on sex-related self-descriptions. Since a combined analysis does not reveal these important differences, separate analyses based on preplanned distinctions were deemed more appropriate.

.001) but not in private conditions ($p > .25$). Self-awareness thus led to more negative self-descriptions in the presence of a female experimenter and more positive self-descriptions in the presence of a male. This was only the case, however, when those self-descriptions were publicly available to those experimenters. Self-descriptions in private conditions were seemingly unaffected by either self-awareness or sex of the experimenter.

General evaluations. Subjects' responses to these five items were combined by subtracting negative (crude, disagreeable) from positive (intelligent, honest, careful) self-evaluations. The means for each of the eight conditions are reported in Table 2. An analysis of variance on these combined scores revealed a significant triple interaction of the same form as that found on the task-relevant items, $F(1, 88) = 9.49$, $p < .005$. Post hoc analyses again indicated that differences in public self-descriptions were primarily responsible for this interaction. Self-awareness interacted strongly with sex of experimenter in public conditions ($p < .001$), but again there were no differences in private ($p > .25$).[7]

Sex-related evaluations. Subjects' responses to these five items were combined by subtracting masculine (masculine, ambitious) from feminine (forgiving, cooperative, jealous) self-evaluations. The means for each of the eight conditions are reported in Table 3. The triple interaction found on the other indexes failed to attain significance on these sex-related

Table 2
Impact of Self-Awareness on General Self-Descriptions: Experiment 2

Self-awareness	Female experimenter		Male experimenter	
	Public	Private	Public	Private
High				
M	13.14	15.48	15.78	14.59
SD	1.81	2.07	1.18	2.51
Low				
M	15.67	15.19	14.63	15.89
SD	1.70	2.34	1.73	2.24

Note. Higher numbers refer to more positive self-descriptions on a 20-point scale; all statistics are based on 12 subjects per cell.

Table 3
Impact of Self-Awareness on Sex-Related Self-Descriptions: Experiment 2

Self-awareness	Female experimenter		Male experimenter	
	Public	Private	Public	Private
High				
M	11.33	11.19	12.59	12.41
SD	1.36	1.30	2.21	1.57
Low				
M	12.37	11.22	12.11	12.89
SD	2.14	2.07	2.03	1.44

Note. Higher numbers refer to more feminine self-descriptions on a 20-point scale; all statistics are based on 12 subjects per cell.

items, $F(1, 88) = 1.78$, $p < 20$. There was, however, a significant main effect for sex of experimenter, $F(1, 88) = 6.98$, $p < .01$. Thus, females described themselves as more feminine in the presence of a male experimenter than in the presence of a female experimenter. This difference did not appear to be contingent on the public quality of the self-description. The most fruitful interpretation of this effect may be in terms of differential trait salience as a function of environmental cues (McGuire, McGuire, Child, & Fujioka, 1978; McGuire & Padawer-Singer, 1976). According to this analysis the present findings of increased feminine trait descriptions in the presence of a male as opposed to a female experimenter would be because of the differential salience of those traits as a function of their situational rarity or distinctiveness.

Mood Self-Descriptions

Subjects' responses to the 10 mood items were combined into three categories for the purpose of analysis: positive, negative, and

[7] Inspection of the means suggests that self-aware subjects in private conditions involving a male experimenter rated themselves slightly less favorably than did non-self-aware subjects. However, insofar as this difference was not significant on this measure —planned comparison $F(1, 88) = 2.55$, $p = .11$—nor even marginal for the task-relevant measure—planned comparison $F(1, 88) = .03$, *ns*—we feel that it is not psychologically meaningful.

defiant. There were no significant effects on any of these indexes.

Discussion

Contrary to the Duval and Wicklund (1972) model, self-awareness did not result in consistently negative self-evaluations and had no apparent effects on reported mood. Instead, the effects of self-awareness appeared contingent on several situational factors. Self-awareness thus interacted with the manipulated anonymity of the response and the sex of the experimenter for both task-relevant and general evaluative self-descriptions.

Consistent with our alternative analysis, the pattern of these results suggests that self-awareness serves to increase sensitivity to self-relevant aspects of the immediate situation. The effects of self-awareness were thus contingent on characteristics of the target for whom the self-descriptions were available.[8] Additional analyses made clear, however, that these effects were restricted to situations in which subjects' self-descriptions were publicly available. Rendering responses anonymous serves the theoretical purpose of eliminating the potential social consequences of the self-descriptions and thus the self-relevance of the sex of the experimenter as a situational cue. Consistent with the present analsis, such a manipulation effectively eliminated the effects of self-awareness.

This is not to say that self-awareness involves "self-presentation" any more than it is to say that self-awareness involves "self-evaluation." The form of the self-aware response is of necessity dependent on the nature of the information that is encoded as self-relevant. Thus, encoding information about past performances in terms of their self-relevance can involve an increased sensitivity to the evaluative connotation of the individual's relationship to the environment. The claim, however, that self-awareness is, in and of itself, a self-evaluative and affect-inducing state is simply unsubstantiated in the literature to date.

Self-Awareness and Causal Attribution

In contrast to an attentional notion of self-awareness, we have proposed that self-awareness involves a particular form of encoding process. Thus, while personally agreeing with the general proposition that attributions follow the individual's focus of attention (Duval & Wicklund, 1972; Jones & Nisbett, 1971; Taylor & Fiske, 1978), we are forced to disagree with the hypothesis that self-awareness affects attribution by increasing *self-focused* attention (Arkin & Duval, 1975; Buss & Scheier, 1976; Duval & Wicklund, 1973). Rather, we would propose that self-awareness affects attribution by increasing the individual's sensitivity to the self-relevant aspects of the immediate situation surrounding the attributional response.

In line with such an analysis, attributional theorists have begun to acknowledge the complex influence of situational factors surrounding attributions of responsibility (Schlenker, 1975; Bradley, 1978; Frey, 1978). Thus, a recent experiment by Frey has demonstrated that when others are aware of a particular outcome, public self-attributions of responsibility are constrained by self-presentational factors of strategic modesty following failure and a complex mix of modesty and self-enhancement following success. On the other hand, private attributions were found to be more responsive to purely defensive concerns.

According to our own analysis, self-awareness should be associated with a heightened sensitivity to just these kinds of self-presentational and defensive concerns. In such circumstances, then, we would predict that the effect of self-awareness on attributions for negative outcomes would depend on the public–private character of the situation.[9]

---

[8] Since only two experimenters were involved, technically it cannot be concluded that the sex of the experimenter was the difference responsible for the experimental effects. However, given the Lefebvre (Note 2) analysis, the brevity of the experimental encounter, and the main effect on sex-related traits, it is reasonable to assume that subjects were responding on the basis of this obvious distinction.

[9] In the present experiment we used hypothetical situations whose outcomes were public knowledge by virtue of having been written by the experimenter and assigned to the subject. The manipulations thus involved public versus private attributions for low-involving situations. Rendering outcomes private or

In contrast, the focus of attention hypothesis would predict a main effect of self-awareness on self-attribution. An experiment was designed to test these opposing predictions by assessing public and private attributions for negative outcomes using procedures based on those developed by Duval and Wicklund (1973) and Buss and Scheier (1976).

Experiment 3

Method

Subjects

The subjects were 52 male undergraduates from Duke University who participated in partial fulfillment of a course requirement. The subject population was restricted to one sex for the sake of convenience. Subjects were run individually and randomly assigned to one of four experimental conditions. Eight of these subjects were eliminated from the analysis on the basis of failure to follow instructions. These subjects were discarded according to predetermined criteria. The remaining subjects were evenly distributed across conditions.[10]

Procedure

Upon entering the experimental room, subjects were seated before a 48-inch × 32-inch (122-cm × 81-cm) mirror that was turned so that its reflective front or nonreflective back faced the subject. All subjects were then introduced to the study in terms similar to those used by Duval and Wicklund (1973) and Buss and Scheier (1976). They were informed that the study involved the development of a social perception questionnaire for use during the following semester and were given a booklet that contained a series of hypothetical situations. They were asked to imagine themselves to be the main character in each of these situations and to respond to each by indicating their degree of responsibility for various hypothetical outcomes. Thus, for example:

> You pull up behind a bus that's stopped at a stop sign, and you want to turn right at this intersection. After waiting 1½ or 2 minutes, the bus hasn't moved. Finally, not knowing what he's going to do, you decide to pull out around him and have to cut back in front to turn right at the corner. Just as you do, he pulls out and runs right into you.

After answering any questions the subject had about this procedure, the experimenter continued with the public-private manipulation.

Public and private conditions. Subjects in the private conditions were asked not to put their names on the booklets and to place the booklets upon completion in the middle of a large pile. Subjects in the public condition were asked to put their names and social security numbers on the booklets, to hand them to the experimenter upon completion, and to anticipate a brief discussion of their responses at the end of the experiment.

Explanation for mirror. For all subjects the experimenter concluded by casually mentioning that he had to share the room with another experimenter and that much of the equipment in the room belonged to the other experimenter's study. He asked the subject not to disturb any of these things, indicating the mirror and various other objects. The subject was then left to work on his own. After completion of the dependent measures, all subjects were carefully probed for suspicion and extensively debriefed.

Dependent measures

The main dependent measures consisted of the percentage of responsibility attributed to the self in each of the five negative-outcome situations used by Duval and Wicklund (1973, Experiment 2). In addition, the amount of time taken to complete the questionnaire was recorded for each subject. This exploratory measure yielded no significant effects and will not be discussed further.

Results

The data were submitted to a mixed-design analysis of variance with two levels each of two between-subjects factors (self-aware vs. non-self-aware; public vs. private) and five levels of the within-subjects factor of hypothetical situation. Contrary to the focus of attention hypothesis, the self-awareness main effect was not significant ($F > 1.00$). However, in accord with our own analysis, the Self-Awareness × Anonymity interaction was significant, $F(1, 40) = 4.38$, $p < .05$.

---

increasing the subject's involvement might well be expected to alter their evaluative connotations and, hence, the character of the self-aware response (cf. Federoff & Harvey, 1976; Frey, 1978).

[10] It was decided in advance to discard any subjects in the public conditions who did not put their name on the booklet (three subjects did not) and any subjects in the private conditions who did not place their booklets in the anonymous pile (two subjects did not).

Table 4
Percentage of Attribution to Self: Experiment 3

Self-awareness	Anonymity	
	Public	Private
High		
M	60.0	51.1
SD	10.9	10.3
Low		
M	53.1	58.2
SD	13.1	9.9

Note. Higher numbers refer to greater attribution to the self on a 100-point scale; all statistics are based on 11 subjects per cell.

Self-aware subjects attributed more responsibility to themselves than non-self-aware subjects in the public condition, but this pattern of results was reversed in private. The only other significant result was a main effect for hypothetical situation, $F(4, 160) = 27.34$, $p < .001$, which simply reflects differences among the hypothetical situations. The means of the conditions collapsed across hypothetical situations appear in Table 4.

Discussion

The present pattern of results suggests that the focus of attention hypothesis by itself is an inadequate conceptualization of the effect of self-awareness on the attribution process: Self-awareness led to greater self-attribution of responsibility than non-self-awareness only under public conditions, the reverse being true in private. Thus, while it may be useful to conceive of causal attributions as affected by the individual's focus of attention (Jones & Nisbett, 1971; Taylor & Fiske, 1978), it is not useful to conceive of the attributional effects of self-awareness in such terms. The present experiment would suggest that self-awareness evokes a much more complex attributional process than merely self-focused attention. Specifically, it is proposed that self-awareness involves an increased sensitivity to the situationally defined meaning of one's actions and, as such, entails a greater responsivity to the presentational constraints and evaluative connotations of self-attributed responsibility. Thus, self-awareness cannot be expected to have a unidirectional impact on attribution (Duval & Wicklund, 1972, p. 103), but rather its effects must be considered in terms of the self-relevant aspects of the attributional context. Anonymity, by rendering different classes of variables self-relevant in the immediate situation, serves to moderate the self-aware response.

Conclusion

In conclusion we would contend that the effects of self-awareness should not be defined by the operation of a particular form of self-regulative process, but rather must be defined in terms of its broader functions of organizing the individual's understanding of the social environment. As such, we would define self-awareness in terms of a heightened sensitivity to particular forms of available information: specifically, the self-relevant contingencies associated with present activity and the self-definitional qualities of information feedback. The three experiments reported in the present article are each attempts to develop the concept of self-awareness along these lines. Thus, Experiment 1 illustrated the particular form of information encoding associated with self-awareness, and Experiments 2 and 3 used conceptual replications of previous research to demonstrate that self-criticism and self-attribution are not characteristic of self-awareness per se, but rather depend on aspects of the immediate situation. Future research, we feel, should be directed toward specifying conditions that determine the self-relevance of various forms of information and thus the effective boundary conditions on the behavioral influences of self-awareness.

Disruptive Effects of Disconfirmed Expectancies About Crowding

Kitty Klein and Bruce Harris
North Carolina State University

The experiment utilized a 2 (high vs. low room density) × 2 (forewarning of a crowded room vs. no forewarning) × 2 (simple vs. complex task) design to examine the effects of anticipation of crowding on task performance. More tasks were attempted and efficiency was higher when expectancies about the crowd were confirmed. Subjects not told to anticipate a crowd who actually worked under high density and subjects warned about a crowd that did not materialize performed most poorly. These differences were largest for the complex task. Baum and Greenberg's results were replicated with the performance data. Perceptions of the experimental room also differed as a function of anticipation, but failure to obtain a Crowding × Anticipation interaction did not support their hypothesis that anticipating a crowd induces identical perceptions to those obtained under actual crowding. The results are discussed in terms of disconfirmed expectancies being disruptive of performance, particularly complex task performance.

Although studies of crowding with human populations continue to proliferate, the dynamics of crowding are still largely a mystery. In particular, the search for inhibitory effects of crowding on task performance has not been very successful (Freedman, Klevansky, & Ehrlich, 1971; Sherrod, 1974; Stokols, Rall, Pinner, & Schopler, 1973). Paulus et al. (1976) have suggested three possible reasons to explain the lack of the clear-cut performance deficits predicted by many researchers. First, density levels may have been too low. Second, task variables sensitive to crowding may not have been used; and third, coping mechanisms have not been considered.

Density Levels

Paulus et al. (1976) have suggested that experimental levels of density have not been sufficiently aversive to affect task performance. However, a review of this literature indicates that task and no-task effects occur in relatively similar ratios of persons to space for the high-density subjects. Differences in density that do exist arise from variations in operationalizing low-density (uncrowded) conditions. Investigators reporting no effects of density on task performance, such as Freedman et al. (1971), allowed high-density (crowded) subjects 3.88 square feet (.36 m^2) per person, whereas low-density subjects were afforded 17.70 square feet (1.65 m^2) per person. Similarly, Sherrod's (1974) high-density subjects had 4.62 square feet (.43 m^2) each, and his low-density subjects, 18.75 square feet (1.74 m^2) each. Stokols et al. (1973) utilized 5.64 square feet (.52 m^2) per person for their high-density conditions and 16.73 square feet (1.55 m^2) per person for their low-density condition.

Density levels in experiments in which performance differences occur are very similar to the levels reported above. Heller, Groff, and Solomon (1977), who found a density effect on task performance when subjects interacted closely with each other, used densities of 3–5 square feet (.28–.47 m^2) per person (high density) and 13–15 square feet (1.2–1.4 m^2) per person (low density).

This research was partially supported by a grant to Bruce Harris from the Student Environmental Studies Fund, North Carolina State University. The authors wish to thank Robert L. Wilson for his assistance with the statistical analysis.

Paulus et al. (1976), who also report effects of density on task performance, allowed subjects 8.8 square feet (.82 m^2) per person (high-density condition) in the second experiment reported, while their low-density subjects had 26.1 square feet (2.4 m^2) per person. Other researchers reporting some effect of density on task performance include Epstein and Karlin (1975), whose high-density condition permitted 2.66 square feet (.25 m^2) per person and whose low density condition allowed 99 square feet (9.2 m^2) per person, and Aiello, DeRisi, Epstein, and Karlin (1977), who utilized 2.50 square feet (.23 m^2) per person (high density) and 48 square feet (4.4 m^2) per person (low density). Unless subjects are extremely sensitive to these variations in density, density per se is not a very satisfactory explanation of the inconsistent results in the effects of crowding on task performance.

Task Variables

A variety of tasks have been used to assess performance in crowded situations. Density has been reported to have no effects on performance on quiz games (Stokols et al. 1973), on anagrams and number cross-outs (Freedman et al., 1971), or on simple arithmetic and Stroop color-word tests (Sherrod, 1974). Sherrod's crowded subjects, however, did not persist as long as uncrowded subjects at an unsolvable puzzle in a noncrowded room following the experiment.

Other investigators have found some evidence of performance decrements as a function of density. Paulus et al. (1976) found that subjects working in groups of eight solved mazes more poorly than subjects working in groups of four. Epstein and Karlin (1975) investigated delayed effects of crowding on simple and complex task performance to determine if crowding would increase arousal. Increased arousal should inhibit complex task performance while facilitating performance on the simple task. No performance differences were obtained on the complex task (Guilford's creative uses test), but previously crowded subjects did perform better on the simple (counting *a*'s) task. In another study of the delayed effects of crowding, Aiello et al. (1977) employed Torrance's unusual use task and line completion tasks. On some subscores of these tasks, previously crowded subjects were less creative than noncrowded ones.

Heller, Groff, and Solomon (1977) did find performance decrements on a collating task as a function of high density and high physical interaction. This task decrement is not surprising in light of the physical obstruction caused by other subjects in the high-density condition.

Taken together, the results of Paulus et al., Epstein and Karlin, and Aiello et al. do suggest that crowding can facilitate simple task performance and interfere with complex tasks. However, the two latter studies measured performance in noncrowded situations following a period in which subjects were or were not crowded. Therefore, the change in conditions rather than the crowding itself confounds their results.

Coping Mechanisms

In Sundstrom's (1975) model of crowding, coping responses are a possible outcome to stress induced by unwanted social inputs.

One variable that may affect coping responses is the ability to anticipate future conditions. Averill (1973) has applied the term "cognitive control" to information concerning impending stress. Averill's review of laboratory and surgery studies in which information was provided led him to conclude that information is generally preferred but that "there is no consistent relationship between such information and initial reactivity" (p. 295). Applied to the problem of crowding and human behavior, informing subjects of crowded conditions has received little attention.

Langer and Saegert (1977) have proposed a concept of attentional overload, which is caused by a combination of close proximity to others and the necessity to predict future environmental states and coordinate behavior. Langer and Saegert recruited shoppers during crowded and uncrowded hours to shop for a list of 50 items. Half the subjects were

warned that crowded supermarkets induce anxiety. The subjects thus informed showed more positive affect and found more of the items on the list. Shoppers during crowded hours attempted fewer items, correctly completed fewer items, and had more negative attitudes. There were no Density × Information interactions.

Although Baum and Greenberg (1975) and Baum and Koman (1976) led some subjects to anticipate a crowded experimental room, the crowd in fact never materialized. Whether the warning facilitated or impeded coping under conditions of actual crowding was not addressed in their research. Subjects who anticipated a crowded experimental room chose different seat positions and were more negative in their ratings of the experimental room and the confederates than subjects who did not anticipate a crowd.

In the present study, the effects of anticipation and the confirmation or nonconfirmation thereof were tested directly. If anticipating a crowd serves to decrease sensitivity to the stress invoked, subjects who are forewarned and do experience the crowd should report less discomfort and perform better than those who do not have advance warning. If anticipation heightens sensitivity to stress, forewarned individuals whose anticipation is confirmed should feel more stressed when the crowd actually appears.

The design utilized two types of tasks for the purpose of testing differences in the ability to cope with a crowd as a function of forewarning. Applying social facilitation theory (Cottrell, Wack, Sekerak, & Rittle, 1968; Zajonc, 1965), if anticipation of a crowd increases arousal, performance on simple tasks should improve, compared to a no-anticipation condition. Likewise, arousal-increasing anticipation should have deleterious effects on complex task performance. If, however, anticipation allows preparation of coping responses, performance on complex tasks should be better as a consequence. On simple tasks, additional coping would have little effect, although there may be some facilitation. Finally, if Baum and Greenberg (1975) are correct regarding the dynamics of crowding, subjects anticipating a crowd should perceive the experimental room differently than those subjects not anticipating a crowd, and these perceptions should be similar to those of crowded subjects not forewarned.

Method

Subjects

A total of 40 male and 40 female undergraduate students enrolled in an introductory psychology course at North Carolina State University participated in the experiment for partial course credit.

Design

The study was a 2 (anticipate crowding vs. no anticipation) × 2 (performing under crowded conditions vs. not-crowded conditions) × 2 (simple vs. complex tasks) experimental design, to test (a) effects of anticipation on performance of tasks and (b) differential effects on complex and easy tasks. Half of the subjects were led to anticipate a crowded environment. The subjects then performed either simple (vowel cross-out) or complex tasks (logical reasoning puzzles) in a small experimental room (1.75 m^2 and 2.70 m high) under crowded conditions (five subjects in the room) or uncrowded conditions (two subjects in the room). Thus, crowded subjects were afforded .61 m^2 (6.61 square feet) per person, whereas uncrowded subjects had 1.5 m^2 (16.50 square feet) per person. Sexual composition of the groups was not controlled. Upon completion of the tasks, subjects were given a questionnaire to assess their perceptions of the experimental room.

The major dependent variable was the subjects' performance (accuracy and speed) on the simple and complex tasks. Twelve ratings of the experimental room itself were also obtained.

Procedure

The anticipation-no-anticipation manipulation began with the recruiting of subjects for an experiment entitled "Logical Reasoning." For the 20 subjects whose expectancies about a crowd were to be disconfirmed, the sign-up sheets contained five lines with three names (fictitious) already written in. Although there was no indication that the experiment involved crowding or even interaction per se, these anticipation subjects were aware that 3 individuals were to report at the same hour. For the remaining 40 subjects, all of whom would be actually crowded, all five lines on the sign-up sheet were filled by subjects themselves.

The 20 subjects who were not led to anticipate a crowd and who were not crowded signed up on sheets containing only two spaces for each session of the experiment. All sign-up sheets requested that friends not serve together.

Subjects arrived at the experiment in groups of either two or five. They were greeted by the experimenter and told to leave all belongings, except for a pencil, on a table in a large room that adjoined a small experimental room, which was 1.75 m^2 and 2.70 m high.

No-Anticipation Condition

The door to the experimental room was partially closed for those subjects not led to anticipate a crowd. When these subjects (no-anticipation group) were ready with their pencils, the door to the experimental room was opened and subjects were led into the room. In the no-crowd condition, two subjects entered the room, which contained two chairs. In the crowded condition, five subjects entered the room, which contained five chairs. The tasks were placed face down on the chairs before the subjects arrived. Subjects then read the instructions of their tasks, either crossing out and counting vowels from a list of random letters or performing five logical word puzzles taken from Wylie (1957). The instructions urged subjects to work as quickly and accurately as possible and to time their own solutions. The experimenter then closed the door for a specified period of time (13 minutes for the vowel cross-out and 23 minutes for the word puzzles). A pretest with the same tasks had indicated that the majority of subjects completed the puzzle task in 23 minutes, whereas the vowel-counting task required only 13 minutes to complete. All subjects in the room worked on the same type of task. Subjects were asked to record their answers on an answer sheet along with the time of day that each puzzle or vowel was completed. That is, subjects wrote down the time, according to a clock hanging in the experimental room, after completing each of the five puzzles, or after counting each of the five vowels. In addition to the starting time, then, five times were recorded on the answer sheet if the subject completed all five tasks.

After the time period elapsed, the experimenter opened the door, collected the papers, and handed the subjects a questionnaire to assess their feelings about the experimental room. This questionnaire consisted of 12 7-point scales; subjects rated the room in terms of its temperature, how pretty it was, illumination levels, stuffiness, size, adequacy, cheerfulness, suitability, dampness, pleasantness, how crowded it appeared, and how much physical discomfort it caused them. When this questionnaire was completed, subjects left the experimental room and were debriefed and thanked.

Anticipation-of-Crowding Condition

For those subjects who were led to believe that five subjects would participate, the procedure was the same with the following exceptions: The door to the experimental room was open when subjects arrived at the large anteroom, and in all cases, five chairs with five papers (the tasks) on them were clearly visible. Before telling the subjects to lay their belongings on a table, the experimenter pointed to the experimental room and stated that the small room was the location of the experiment. When subjects were ready with their pencils, the experimenter showed them a list of five names, and asking each subject his/her name, conspicuously checked it off. In the condition in which crowding occurred, five subjects entered the experimental room, and the door was closed. In the condition in which the anticipation of crowding was not confirmed, the two subjects entered the experimental room after having their names checked off the list of five names and were told by the experimenter that he would let the others in as soon as they arrived. The experimenter then closed the door, leaving the two subjects to work in a room with three empty chairs. As in the no-anticipation condition, subjects were debriefed and thanked after completing the final questionnaire.

Dependent Measures

The tasks were scored in the following manner: For the vowel-counting task, there were five correct answers (one for each vowel), and a subject was either correct or incorrect in recording the frequency of each vowel. Of the five logical word puzzles, two required only one answer to solve the puzzle correctly. Of the remaining three puzzles, one required two answers for successful completion, one required three answers, and the third required four answers. To be scored correct, all answers of the given puzzle had to be shown correct. In the analyses that follow, standard scores were computed using the overall means of all subjects assigned to the puzzle conditions and of all subjects in the vowel conditions.

Three different measures of performance were analyzed: simple number of correct puzzle solutions and correct vowel counts; number of puzzles and vowel problems attempted; and the number of minutes spent for each solution on both tasks. Because of the nature of the instructions, the minutes/task measure was treated as an index of efficiency similar to Paulus, Gatchel, and Seta's (1978) efficiency (rate). In order to test both the puzzle and the vowel data in an analysis that included type of task as an independent variable, each subject's scores were transformed to standard scores, using the overall means of all subjects assigned to the appropriate task condition.

Results

Preliminary Analyses

All three dependent measures were first analyzed to determine if there were any effects of sex of subject, sexual composition of the group, or the groups themselves. Subject

sex, crowding, and whether the crowding was anticipated were used as factors in a multivariate analysis of variance (MANOVA) on the three measures for each task. Neither main effects of sex nor interactions were found for either the puzzles or the vowels.

The groups, which consisted of either two persons (uncrowded) or five persons (crowded) were further categorized as all male, all female, or mixed in order to determine whether sexual composition of the group affected performance. Again, a multivariate analysis of variance indicated neither a main effect nor interactions for sexual composition for either task.

Finally, a MANOVA using crowding, anticipation, and groups as a nested factor was conducted for each task. The groups effect was not significant in either the puzzle or the vowel conditions. Because of the lack of effects for sex, sexual composition of the group, or the groups themselves, the data below are collapsed across these variables.

Task Performance

The effects of forewarning of a crowd on simple and complex task performance was tested in a three way MANOVA (Anticipation × Crowding × Task) using the number of correct solutions, the number attempted, and the time per correct solution (efficiency). There were significant interactions: Anticipation × Crowding, $F(3, 70) = 3.81$, $p < .01$; Crowding × Task, $F(3, 70) = 2.77$, $p < .05$; and Anticipation × Crowding × Task, $F(3, 70) = 2.58$, $p < .06$; and a significant main effect of tasks, $F(3, 70) = 74.74$, $p < .0001$.

The univariate tests on each dependent variable indicated that on the number correctly completed, only a task effect was obtained. Subjects who counted vowels actually got fewer correct than did subjects who solved puzzles—1.40 correct for the vowel count versus 1.97 for the puzzles, $F(1, 72) = 6.89$, $p < .01$. This difference may arise from the different nature of the feedback involved in each task. The vowel counting offered no check on the correctness of the solution; that is, errors in counting were unlikely to be detected. An incorrect guess concerning the logical puzzle solution could be more easily rejected, because subsequent guesses would prove incorrect.

Table 1
Mean Number of Tasks Attempted as a Function of Forewarning and Crowding

Condition	Crowded	Not crowded
Anticipation	$4.6_{a,b}$	4.15_{b}
No anticipation	$4.4_{a,b}$	4.75_{a}

Note. For each mean, $n = 20$. Means with different subscripts differ significantly using Duncan's multiple-range tests. Number of tasks attempted (both puzzles and vowels) ranged from 3 to 5; maximum possible = 5.

On the number of tasks attempted, the Anticipation × Crowding interaction was significant, $F(1, 72) = 6.03$, $p < .016$. Across both tasks, subjects whose expectancies were confirmed attempted more problems than did subjects whose expectancies were disconfirmed. Subjects who were forewarned about a crowd and were actually crowded tried more tasks than subjects forewarned and not actually crowded. Subjects not forewarned and not crowded tried more tasks than subjects surprised by the crowd (see Table 1).

On the third dependent variable, the amount of time spent per correct solution, the three-way interaction (Anticipation × Crowding × Task) was significant, $F(1, 72) = 5.11$, $p < .02$. As can be seen in Figure 1, it is clearly in the complex task that crowding and anticipation had their greatest effect.

To examine these results in each task separately, a 2 (anticipation – no anticipation) × 2 (crowded – not crowded) analysis of variance was performed on all three dependent variables. In this analysis, no effects of anticipation or crowding appeared for either the number of vowels correctly counted or the number attempted. There was an effect of anticipation on efficiency (number of minutes spent working on each letter) on the vowel-counting task, however, $F(1, 36) = 4.38$, $p < .04$. Subjects who anticipated a crowd spent more time on each vowel count than subjects not anticipating a crowd (3.14 minutes vs. 2.68 minutes per vowel count).

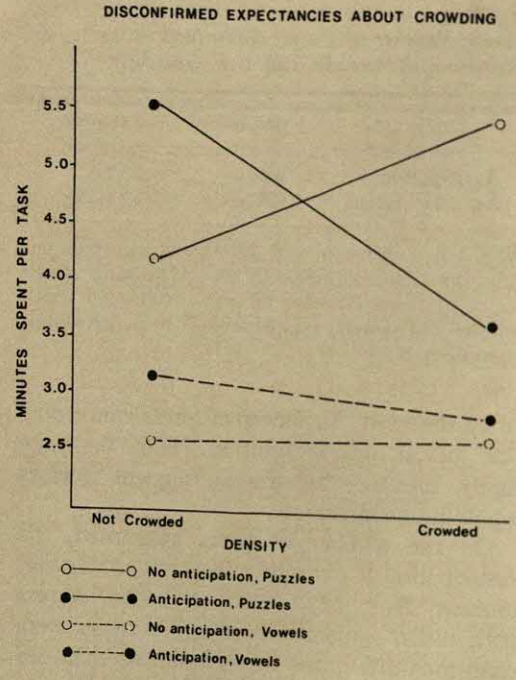

Figure 1. Efficiency as a function of density, anticipation, and type of task.

On the puzzle task, the Crowding × Anticipation interaction was significant on both the number of puzzles attempted, $F(1, 36) = 7.04$, $p < .012$, and on the mean time per solution, $F(1, 36) = 9.10$, $p < .004$. As can be seen in Table 2, fewer attempts to solve were made when crowding was expected but failed to occur and when crowding was not expected but did occur. In both these cells, subjects were caught "unaware." Those who had been forewarned that they would be performing in a high-density environment but actually worked in low-density conditions had their expectancies about the experimental session disconfirmed. Likewise, subjects who were not forewarned suddenly found themselves working in a crowd.

The same pattern of effects appears in the time required for each solution (see Table 2). In this interaction, subjects who expected a crowd and were indeed crowded or who did not expect a crowd and were not crowded performed more efficiently than subjects who were surprised by the experimental conditions.

Perceptions of the Experimental Room

To determine whether the anticipation factor also affects perceptions of the environment, a multivariate analysis of variance was performed on the scales subjects used to rate the experimental room. As in Baum & Greenberg's (1975) study, there was a significant main effect of anticipation, $F(12, 65) = 2.36$, $p < .012$.

Univariate tests of anticipation indicated that anticipation had significant effects on how hot, $F(1, 72) = 7.32$, $p < .01$; how comfortable, $F(1, 72) = 4.65$, $p < .05$; how adequate, $F(1, 72) = 7.99$, $p < .01$; and how suitable, $F(1, 72) = 10.26$, $p < .01$, the room appeared (see Table 3). Subjects who anticipated a crowd rated the room as hotter, less comfortable, less adequate, and less suitable than subjects who were not forewarned. Whether or not the crowd actually materialized also approached significance on the room perception data, $F(12, 65) = 1.82$, $p < .06$. The only rating on which crowding had a significant main effect was the perception of how crowded the room appeared, $F(1, 72) =$

Table 2
Mean Number of Puzzles Attempted and Time (in minutes) per Solution as a Function of Forewarning and Crowding

Condition	Crowded		Not crowded	
	No. attempted	Time	No. attempted	Time
Anticipation	4.80_a	3.77_x	4.20_b	5.63_y
No anticipation	4.20_b	5.21_y	4.80_a	4.25_x

Note. For each mean, $n = 10$. Means with different subscripts differ significantly using Scheffé tests. Time ranged from 1.80 minutes to 7.66 minutes; maximum possible = 23 minutes. Number of puzzles attempted ranged from 3 to 5; maximum possible = 5.

14.50, $p < .001$. Crowded subjects did perceive the room as more crowded than noncrowded subjects ($M = 4.25$ vs. $M = 2.62$, respectively).

The multivariate F for the Crowding × Anticipation interaction was not significant, $F(12, 65) = 1.03$, $p < .4$. Type of task also had no effect on room perceptions, even though puzzle subjects spent a longer time in the experimental room than did subjects counting vowels.

Discussion

Performance

The present data raise a number of issues heretofore unaddressed in either the social facilitation or crowding literature. Subjects in uncrowded conditions who were not misled to anticipate a crowd performed better on both simple and complex tasks compared to subjects warned of a crowd that failed to materialize. Likewise, being crowded when one was not forewarned hurt performance on simple and complex tasks compared to working in crowded conditions with forewarning, although these differences were not significant.

On the simple vowel-counting task, anticipation decreased efficiency for both crowded and uncrowded conditions. This finding fits neither a learned drive (Cottrell, 1972) nor a distraction explanation (Baron, Moore, & Sanders, 1978) of social facilitation. If forewarning about crowding acts to increase arousal, forewarned subjects' performance on the simple vowel-counting task should have been superior to the performance of subjects given no information.

Nor are these results analogous to those reported by investigators concerned with the effects of information about impending stress. In such studies, the amount or kind of information has varied, rather than its accuracy. As Averill (1973) notes, predictability has been found both to enhance and to inhibit stress reactions. However, in the data presented here, subjects with equivalent information about the experimental setting (that is the anticipation–crowded and the no-anticipation–not-crowded conditions) were not equally efficient vowel counters.

Table 3
Mean Ratings of the Experimental Room as a Function of Anticipating a Crowd

Condition	Descriptive dimension			
	Hot	Comfortable	Adequate	Suitable
Anticipation	3.70	4.47	4.50	4.25
No anticipation	4.20	3.67	3.42	3.02
F	7.32**	4.65*	7.99**	10.26**

Note. $n = 40$. Ratings are on a 7-point scale. The lower the mean, the closer to the descriptive dimension.
* $p < .05$. ** $p < .01$.

Further indication that anticipation does not affect the actual crowding experience in any straightforward manner is found in the data from the complex task conditions. Performance on the puzzles was affected by whether the anticipation was confirmed, not by anticipation itself. Subjects who anticipated and did experience the crowd performed better than those who had no advance warning of the crowd. For crowded subjects then, anticipation enhanced performance. Subjects not forewarned and not crowded performed equally well, but those who mistakenly anticipated a crowd were less efficient.

These complex task results fit a social facilitation paradigm only if one assumes that it is the disconfirmation of an expectancy that contributes to arousal or distraction. The disconfirmation explanation also helps explain the data in terms of the information about aversive stimuli research. Lack of predictability decreases complex task efficiency.

As in previous studies (Freedman et al., 1971; Sherrod, 1974; Stokols et al., 1973), no differences in performance were found as a result of crowding alone. Experiments (Aiello et al., 1977; Epstein & Karlin, 1975) in which delayed effects of crowding are reported may inadvertently have confounded expectations about crowding in the test situation with the pretest density manipulation. Subjects exposed to a crowd may anticipate further crowding; their surprise at their subsequent isolation during task performance

may affect their performance as much as the crowd they previously experienced.

The performance data only partially replicate the findings of Langer and Saegert (1977). In that study, forewarning proved beneficial whether or not crowding actually occurred. This discrepancy may arise from the different nature of the tasks used or the type of forewarning manipulation. Langer and Saegert explicitly warned subjects that crowding induced anxiety; in the present study, the forewarning was information only, and subjects were not led to expect any particular psychological consequences.

Room Perceptions

The room perception data do show main effects of anticipation. On several scales, subjects who anticipated the crowd rated the room as more uncomfortable than subjects not forewarned. The room ratings were made at the end of the experimental session. The absence of any Crowding × Anticipation interaction on room perceptions suggests that the density levels used here did not create additional discomfort beyond that generated by the forewarning at the beginning of the experiment.

Baum and Greenberg's (1975) contention that crowding and anticipation are dynamically similar states receives equivocal support in the present results. A strict test of Baum and Greenberg's hypothesis would require similar perceptions from subjects anticipating a crowd that did not materialize and subjects who did not anticipate a crowd but did find one. Complete support for this interpretation of Baum and Greenberg's hypothesis would necessitate an interaction between crowding and anticipation such that anticipating–not-crowded subjects perceived the room in the same way as nonanticipating–crowded subjects. No univariate tests of the Crowding × Anticipation interactions on the room ratings were significant. Thus, although anticipation did cause differences in perceptions of the room, anticipating a crowd did not lead to the same perceptions as actually being in one.

There is more support for Baum and Greenberg's proposal in the performance data. Subjects who anticipated a crowd that never materialized did not perform significantly differently than subjects not anticipating a crowd who worked under crowded conditions.

In the present study, reliable interactions were obtained despite the indirect nature of the forewarning and a crowding experience that was perceived as only moderately uncomfortable. Whether anticipation would have had similar effects if the crowding had truly been stressful has yet to be determined. The degree to which the forewarning is simply an objective description of future conditions, advises on coping mechanisms, or forecasts physical or emotional distress as a consequence of severe crowding also should be examined. Human beings encounter naturally crowded situations both with (e.g., holiday shopping) and without (e.g., delays in air terminals) forewarning. It would seem appropriate to investigate under what conditions different types of foreknowledge increase the ability to cope with a crowd.

Persistence of Opinion Change Induced Under Conditions of Forewarning and Distraction

William A. Watts

University of California, Berkeley

Lewis E. Holt
Stanislaus State College

Ninety-six high school students participated in a study investigating the immediate and delayed effects of forewarning of persuasive intent. It was predicted that subjects would change less immediately after reading persuasive communications because the forewarning would serve as a discounting cue, but that over time, they would tend to forget or dissociate this cue, thus allowing the full impact of the communication to emerge. The results strongly supported this hypothesis.

A second experiment involving 104 high school students was conducted to replicate the first study and to extend the same reasoning to the case of distraction. Distraction was expected to facilitate immediate opinion change, presumably because of interference with counterarguments; but because of its detrimental effect on comprehension and a presumed tendency for subjects to think of opposing arguments after leaving the experimental situation, the change was expected to dissipate more rapidly than in the nondistracted conditions. The data confirmed predictions regarding both forewarning and distraction.

Although forewarning of persuasive intent has been studied extensively (e.g., McGuire, 1966, 1969; McGuire & Papageorgis, 1962; Papageorgis, 1968; Petty & Cacioppo, 1977), there have been no reported investigations of its long-term, or delayed, effects. If forewarning has an immediate detrimental effect on opinion change, which is by no means universally found (e.g., Papageorgis, 1968), there is reason to believe that the inhibiting influence will dissipate over time, thus allowing a greater delayed than immediate impact of the message. That is, if forewarning leads subjects to think of counterarguments either before or while reading a communication (e.g., McGuire & Papageorgis, 1962; Petty & Cacioppo, 1977), arouses psychological reactance (Brehm, 1966; Hass & Grady, 1975), or causes the subjects to perceive the communicator as less fair (e.g., Hass & Grady, 1975), an immediate reduction in persuasive impact should result. However, unless the forewarning significantly interferes with learning the message content, which seems unlikely (e.g., Freedman & Sears, 1965), subjects may tend to forget or spontaneously dissociate these initial reactions over time, thus allowing the full persuasive impact of the material to emerge. For example, Hass and Grady (1975) point out that despite the presence of reactance, one may be persuaded by the informational value of the arguments presented by the communicator. It would logically follow that given compelling arguments, once the initial reactance subsides, the impact of the information should produce increased opinion change over time (e.g., Gruder et al., 1978). Similarly, if forewarning tends to create the perception of a biased communicator (e.g., Hass & Grady, 1975), as this discounting cue becomes dissociated from the message over time, a delayed increase in agreement might be expected. This is analogous to the

Sincere appreciation is extended to Robert S. Wyer, Jr., and Richard E. Petty for their most helpful and astute comments when reading earlier versions of this manuscript.

original interpretation of the sleeper effect in persuasion (Hovland, Lumsdaine, & Sheffield, 1949).

Issue Involvement as a Factor in Forewarning

In attempting to account for the conflicting results in studies of forewarning, Papageorgis (1968) has differentiated between cases involving the mere prior announcement of the topics and directions of persuasive communications, termed "warnings," and those in which the subjects are specifically told that the experiment deals with persuasion, dubbed "persuasion contexts." He hypothesized that persuasion contexts served to reduce the impact of communications about issues with high involvement or those that concern controversial topics or make emotional appeals, whereas for communications about issues with low involvement or those that argue about cultural truisms or make factual appeals, persuasion contexts have no more effect than disguised (no forewarning) contexts when other characteristics of the persuasion situation are neutral.

There are at least two theoretical reasons for expecting different results for issues of high and low involvement: (a) Psychological reactance (Brehm, 1966) should be greater for important issues, and (b) subjects are probably less able and/or motivated (e.g., Vinokur & Burnstein, 1978) to think of counterarguments in the case of cultural truisms or esoteric topics. Dean, Austin, and Watts (1971) found no support for these conjectures; however, their studies were limited in the sense that each employed only two issues—one high and the other low in involvement. Naturally, the topics varied in a number of other respects that may have influenced the obtained results.

In the present study, eight issues were used in an attempt to minimize the aforementioned problem: Four dealt with familiar, controversial issues; and the others, with esoteric topics. An example of the former would be the proliferation of nuclear weapons, and of the latter, the increasing length of the geological day. If the reasoning of Papageorgis (1968) and perhaps that of Apsler and Sears (1968) is correct, the immediate effects of forewarning should be to inhibit change on the familiar topics and to facilitate it or have no effect on subjects' opinions concerning the esoteric issues.

The first study was designed to test these conjectures. Since each subject read messages on four different topics, it was not feasible to warn them of the positions advocated in each case. Rather, subjects were warned of the persuasive intent (Papageorgis, 1968) of the materials they were about to read. This manipulation has been used in several previous studies (e.g., Hass & Grady, 1975; Kiesler & Kiesler, 1964). Under these circumstances there is no opportunity for anticipatory counterarguing (Petty & Cacioppo, 1977); consequently, there is no reason for a delay between forewarning and receipt of the messages (e.g., Hass & Grady, 1975). Similarly, there is little opportunity for anticipatory belief change (e.g., McGuire & Millman, 1965), since the subjects are unaware of the topics and positions advocated until the message are received.

Distraction as a Variable Influencing Persistence of Opinion Change

A second study focused on the single and joint effects of forewarning and distraction. Whereas forewarning has been shown previously to facilitate production of counterarguments (e.g., Petty & Cacioppo, 1977), distraction apparently interferes with this process (e.g., Baron, Baron, & Miller, 1973; Festinger & Maccoby, 1964; Osterhouse & Brock, 1970; Petty, Wells, & Brock, 1976). Therefore, distraction should influence positively the yielding component of persuasion (e.g., McGuire, 1968, 1969; Wyer, 1974, chap. 7), thus rendering the person more susceptible to influence if the message is adequately comprehended.

However, there is considerable evidence that distraction also interferes with comprehension (e.g., Haaland & Venkatesan, 1968; Petty et al., 1976; Regan & Cheng, 1973; Zimbardo, Snyder, Thomas, Gold, & Gurwitz, 1970). Whenever a variable influences the reception and yielding components of persuasion in opposite directions, the resultant effect often may be nonmonotonic (e.g., McGuire,

1968, 1969; Wyer, 1974, chap. 7). That is, a moderate amount of distraction will facilitate opinion change because the reduction in counterarguing more than offsets the decrement in comprehension. As distraction increases, however, the loss in comprehension should become greater, thus leading to a decrease in opinion change, since, in the extreme case, one cannot conform to the position advocated in the communication without understanding the side taken. Even though the immediate effect of distraction may be to facilitate opinion change, there are at least two reasons to expect the gain to be short-lived. First, several prior studies indicate that experimental treatments affecting initial learning influence persistence of induced opinion change as well (see Cook & Flay, 1978). Thus, the decay in opinion change may be quite rapid, depending on the extent that distraction interferes with comprehension. Note that in the case of distraction, consideration of its effects on comprehension lead to the exact opposite prediction of that derived for forewarning, namely, that the induced opinion change would dissipate more rapidly for distracted subjects because of poorer learning of the message content.

Another reason for more rapid decay of opinion change under conditions of distraction hinges on postexperimental counterarguing. Once the subject has left the experimental room, he or she is free of distraction and in a position to reflect on the persuasive messages. It seems likely that in the process, the individual would be able to think of a greater number of opposing arguments that would serve to dampen his/her newly formed opinion. Naturally, the people who were not distracted may also cogitate upon the issues afterward and think of additional counterarguments. However, the latter should be smaller in number and have less impact because these individuals would already have considered many of the counterarguments during the experimental session and have taken them into account at that time (e.g., Vinokur & Burnstein, 1978; Vinokur, Trope, & Burnstein, 1975). Actually, the distracted subjects may be more motivated to think about the topics after the experimental session, since reading communications under conditions of distraction may require greater effort (e.g., Baron et al., 1973), and if subjects have worked harder on a task, it would seem likely that they would feel increased involvement.

To test these conjectures, in the second study, forewarning versus no forewarning plus distraction versus no distraction were varied orthogonally so that their single and joint effects on immediate and delayed opinion change could be examined.

Experiment 1

Method

Subjects and Design

The subjects consisted of 96 students from four senior-level high school classes who participated in both sessions of the experiment, separated by a 1-week interval, during their normal class periods. There were approximately equal numbers of males and females.

Eight messages were randomly divided into two subsets of four each with the restriction that they had to contain two familiar and two esoteric topics. These forms of the materials were alternated. Subjects read one of the subsets of persuasive messages and then stated their opinions on all eight issues. Hence, each person served as an experimental subject on four issues and as a control on the remaining four topics. A $2 \times 2 \times 2 \times 2$ factorial design was used involving one between-subjects variable (forewarning vs. no forewarning) and three within-subjects variables (message type: esoteric vs. familiar, time of measurement, and experimental vs. control). The order of presentation of the two types of messages was counterbalanced. Since subjects were randomly assigned to experimental treatments, a posttest-only design was employed, inasmuch as a pretest itself would serve to some extent as a forewarning of persuasion.

Procedure

The study was represented as an investigation of factors related to learning and retention of written communications. It was explained that such factors as the controversiality of the topics and whether essays were written in an emotional or factual manner were thought to play important roles in determining learning efficiency and recall of message content. In the first session, subjects read four persuasive communications, each averaging about 300 words in length. Two of the messages in each set dealt with

familiar, somewhat controversial topics, whereas the other two concerned esoteric issues.[1]

The forewarning manipulation was incorporated into the written materials to facilitate random assignment of this variable to subjects within a given class. Approximately one half of the subjects received instructions indicating that the messages were designed to change their opinions on certain issues. The directions were worded as follows:

> On the following pages you will find four passages; they are designed to persuade you. Each message will attempt to change your opinion about a particular topic. To ensure a careful reading, please pick out and underline the shortest phrase, or phrases, in each paragraph which convey the idea expressed. As you know, we are interested in the manner in which subject matter affects information processing; and its persuasive intent is thought to be one important factor. Your close attention to the task will contribute to a more adequate understanding of the process. Thank you.

In the instructions for the nonforewarned subjects, all references to the persuasive intent of the materials were deleted, and the previous verbal statement regarding the influence of familiarity and controversiality in information processing was repeated. The time interval between warning and exposure to the persuasive materials was no more than a few seconds, which Hass and Grady (1975) have shown is quite adequate.

After the four messages were read and the materials collected, subjects' opinions were assessed on all eight issues, thus providing no message control data for four topics. The justification of the opinion measurement was in terms of obtaining indices of controversiality of the issues for the population being studied. Opinions were measured on 100-point probability-of-truth scales calibrated in units of 10, ranging from 0 (Very improbable) to 100 (Very probable). The rating scale was presented immediately below each statement. One opinion item pertained to each topic. Examples include "The number of countries producing nuclear weapons is increasing rapidly" and "A substantial falling off in consumer purchasing power in the United States is presently occurring." After the opinion ratings had been collected, each subject completed a multiple-choice test of comprehension, with three items pertaining to each issue. In addition, subjects rated, on 7-point scales, how fair the articles were, how interesting they found the subject matter, and to what extent they were thinking of opposing arguments as they read the communications. Afterward, all subjects were thanked for their participation, and no mention was made of any follow-up testing.

In the second session, after a 1-week interval, subjects again supplied opinion ratings and completed the comprehension test. Thereafter, the true purpose of the study was explained. Since the experiment was represented as one dealing with comprehension and retention of message content as functions of controversiality and other characteristics of the material, the second request for opinion ratings was justified on the basis of providing indices of temporal fluctuations, since controversial issues are often quite changeable.

Results and Discussion

The opinion data were analyzed with a $2 \times 2 \times 2 \times 2$ factorial analysis of variance consisting of one between-subjects variable (forewarning vs. no forewarning) and three within-subjects variables (message type: esoteric vs. familiar, time of measurement, and experimental vs. control). To facilitate analysis, data from two subjects in the forewarned condition were randomly discarded in order to obtain equal cell frequencies. The overall persuasive impact of the messages and the effects of the experimental treatments were determined by comparing the final opinion scores for the message topics with the no-message control scores. Within the familiar and esoteric message conditions, subjects' opinion scores were averaged across the two issues.

Message Effects

The overall persuasive effect of the messages, without regard to experimental conditions, was impressive, $F(1, 92) = 62.92$, $p < .01$, for the main effect of experimental versus control treatments. As expected, subjects changed their opinions considerably more on the low-involvement, esoteric issues than on the familiar, more involving ones; $F(1, 92) = 13.75$, $p < .01$, for the interaction effect of message type in the experimental versus control conditions. Although the interaction between forewarning and experimental versus control conditions was significant, $F(1, 92)$

---

[1] The four familiar topics dealt with the proliferation of nuclear weapons, economic aid to developing African nations, the increasing number of professionally trained ministers in the United States, and the current decline in consumer purchasing power. The esoteric issues concerned the increasing length of the geological day, the effectiveness of a new drug on the peripheral vascular circulation in humans, the amount of fuel and power in Zambia, and the influence of New York City banks on the yield of U.S. government bonds.

Table 1
Mean Opinion Scores for Each of the Experimental and Control Conditions

	Familiar issues				Esoteric issues			
	Not forewarned		Forewarned		Not forewarned		Forewarned	
Condition	Immediate measurement	Delayed measurement	Immediate measurement	Delayed measurement	Immediate measurement	Delayed measurement	Immediate measurement	Delayed measurement
Experimental	72.76	61.92	61.38	65.74	73.40	63.19	57.34	63.62
Control	55.32	55.21	63.62	60.32	44.04	49.36	45.42	49.68

Note. These means are averaged across the two similar issues in each condition and are based on 100-point scales ranging from 0 (Very improbable) to 100 (Very probable). Cell *n*s = 47.

= 9.93, $p < .01$, the second-order interaction involving forewarning, message type, and experimental versus control conditions that would be expected from the work of Papageorgis (1968) was trivial ($F = .10$). That is, although subjects changed their opinions much more when the topics were low rather than high in involvement, compared to no-message controls, the inhibitory effects of forewarning were the same for both types of issues. While the data offered no support for Apsler and Sears' (1968) multiplier hypothesis, one should keep in mind that these investigators warned subjects of the specific topics and sides to be taken, whereas we simply forewarned them of persuasive intent without specifying the topic or side. Finally, in retrospect, it seems that perhaps even the familiar issues were relatively low in personal involvement, particularly for the population studied. This may explain the weakness of some of the anticipated effects.

Persistence of Forewarning Effects

The primary hypothesis tested in the present study involved the interaction between forewarning and time of measurement. It was predicted that forewarning would inhibit the immediate change resulting from the persuasive communications, but that this effect would be short-lived, and over time, the forewarned group would show an increment as the forewarning is forgotten or spontaneously dissociated, whereas those subjects who were not forewarned would show a typical decay. The test for this hypothesis is the Forewarned × Time × Experimental versus Control interaction, which was significant beyond the .01 level, $F(1, 92) = 22.12$. The pattern of means displayed in Table 1 shows that the direction of this interaction was as predicted, with subjects who were forewarned showing an initial decrement of 13.72 points, averaged across message type, compared to those individuals who were not forewarned, and, indeed, changing only trivially more than the no-message controls. After a week elapsed, however, the forewarned subjects had shown an absolute increase of 5.32 points and were now slightly higher than the nonforewarned group and substantially higher than their controls. Although the data show a relative sleeper effect (Cook & Flay, 1978), the increase did not reach significance when tested by Dunn's (1961) method; thus, an absolute sleeper effect was not obtained.

It is interesting to note the similarity of the delayed measurement means for the experimental treatments, indicating that regardless of the immediate effects of forewarning, the long-term (1-week interval) results are about the same as for subjects who were not forewarned. The findings cannot be attributed to all persons reverting to the control level during the time interval, since the overall delayed experimental mean, aggregated across treatments, was much higher than for the similar control conditions (e.g., 63.62 versus 53.64).

Forewarning Effects on the Control Issues

As stated in the introduction, it would have been virtually impossible for anticipatory belief change (such as that observed by McGuire & Millman, 1965, and others) to have occurred in the present study, since neither the topics nor the positions advocated were known prior to being read by the subjects. It is quite conceivable, however, that the forewarning might have led to some general reaction at the time of completing the postexperimental test, particularly since each subject served in both the experimental and control conditions. It can be seen in Table 1 that control subjects in the forewarned conditions were more favorable toward the familiar issues, both immediately afterward and during the delayed testing, than those subjects who were not forewarned; but no such effect occurred for the esoteric topics.

Dinner, Lewkowicz, and Cooper (1972) found greater change in high-self-esteem subjects anticipating communications concerning familiar topics, presumably so they would avoid appearing gullible. While Dinner et al. announced the topics and sides to be taken, it is possible that in the present study, subjects surmised the directions that would be advocated on the control issues and responded accordingly to avoid subsequent change should they later receive communications on these topics. However, considering the relative lack of sophistication of the high school subjects, it seems far more probable that this was just a chance occurrence, particularly since it did not appear for the esoteric topics and was not replicated in the second study for familiar issues.

Comprehension

These data were analyzed in the same manner as the opinion scores, with subjects' responses averaged across the two topics within each experimental condition. Naturally, there were no control scores for this variable, since subjects could only be asked to recall what they had read. The data indicated a slight superiority across time for students in the forewarned conditions, who obtained a mean of 1.40 correct responses out of a possible 3, compared to 1.17 correct for those who were not forewarned. The difference between these means is of borderline significance $F(1, 92) = 3.85$, $p < .06$. Forgetting during the 1-week interval was trivial ($F = 1.02$), and the only other significant effect was markedly superior memory for the familiar, compared to the esoteric, issues, $F(1, 92) = 24.60$, $p < .01$.

Reactions to the Persuasive Communication

Three questions were included in the immediate posttest to measure subjects' reactions to the persuasive communication: "How fair and unbiased did you find the communications?"; "How interesting did you find the messages?"; and "As you read the messages, to what extent did you find yourself thinking of arguments on the other side?" Subjects responded to each question by checking a 7-point scale ranging from 1 (Not at all) to 7 (Very).

Only the differences in ratings of fairness reached significance ($t = 3.07$, $p < .01$), with subjects who had been forewarned of the persuasive nature of the communications rating the contents as considerably less fair and unbiased ($M = 3.20$) than their nonforewarned counterparts ($M = 4.28$).[2] These results are similar to those found by Dean et al. (1971) with regard to messages attributed to positive sources and provide further corroboration for the discounting cue interpretation of the obtained sleeper effect in the forewarned condition. Although the obtained means for counterarguing were in the expected direction (4.00 for forewarned subjects vs. 3.46 for those persons not forewarned), the difference did not approach significance and offered no support for the conjecture that subjects whose defenses had been aroused by forewarning would think of more counterarguments while reading the communications.

In summary, these data provide strong

[2] Since these last three questions appeared separately on the last page of the booklet, some subjects apparently overlooked them and failed to respond. Consequently, the cell *n*s were reduced to 45 for the forewarned individuals and 36 in the case of those persons who were not forewarned.

evidence for the predicted sleeper effect due to forewarning of persuasive intent. They are readily interpreted in terms of forewarning serving as a discounting cue to acceptance without interfering with learning—a cue that over time (1 week) subjects are likely to forget or spontaneously dissociate, thus allowing the persuasive materials to reach their full impact. Indeed, this method of studying the sleeper effect may be superior to the classic approach of attributing a compelling message to a negative source, since the latter often must arouse feelings of incredulity on the part of the subjects.

Experiment 2

The second study was designed to replicate the first and, in addition, to test the conjecture that while moderate distraction may facilitate immediate opinion change, the latter will rapidly dissipate, because once removed from the distraction conditions, the person will think of additional counterarguments to the communications, and, to some extent, comprehension of the persuasive messages will have been impaired. Each of these factors should operate to shorten any immediate advantages realized.

Method

Subjects and Design

One hundred four high school students participated in both sessions of the experiment, which were held 1 week apart, during their normal class periods. The number of males and females was divided about equally. Each subject read two out of four persuasive messages and then stated his or her opinion on all four, thus providing control scores for two issues. Only one of the issues was read under conditions of distraction, and subjects were either forewarned or not for both issues.

A posttest-only design was employed, with subjects randomly assigned to the experimental conditions. Since distraction was a within-subjects variable, the order of presentation of the two messages (under conditions of distraction and nondistraction) was counterbalanced. The two levels of forewarning and distraction and the two times of measurement constituted a $2 \times 2 \times 2$ factorial design with one between-subjects (forewarning) and two within-subjects treatments. An equal number of subjects (52) served in each condition.

Procedure

As in Experiment 1, the study purported to investigate the effects of types of reading material on retention of message content.

In the first session, each subject read two (randomly selected from a set of four) persuasive messages averaging about 300 words in length. These communications dealt with current topics of moderate familiarity, namely, economic aid to African nations, consumer purchasing power in the United States, the increasing number of trained ministers, and proliferation of nuclear weapons. One message was read under normal circumstances and the other under distraction conditions. The distraction was designed to be relatively neutral and consisted of printing the messages in white type on a black background, rather than the conventional black on white. Pretests had shown that this reverse negative procedure was indeed distracting without being annoying, at least for the relatively short periods of time involved.[3] Furthermore, the distraction was quite consistent with the rationale given that the study investigated the influence of such factors on comprehension.

As in the previous study, the forewarning manipulation was incorporated into the written materials in order to facilitate random assignment of subjects within a given class to the different experimental conditions. For one half of the subjects, the instructions forewarned that the communications were designed to change their opinions on certain issues. For the other half, these statements were deleted; otherwise the same directions were issued to the forewarned and nonforewarned groups. All other aspects, including the purported rationale for the second opinion ratings and comprehension testing were identical to those in Experiment 1. Of course, as before, the true purpose of the experiment was eventually revealed.

Results

In the first study, the types of messages introduced the possibility that subjects could hold different initial opinions for the esoteric and familiar topics, as indeed was the case. Therefore, inclusion of the control data was necessary for the main analysis. Since no such variables were included in the second study, and there was no counterpart for the distraction manipulation under the control

[3] The materials were pretested by asking subjects to rate the extent to which they found themselves distracted or annoyed. In addition, immediate comprehension was found to be poorer for the distracted subjects—a characteristic that has been associated with distraction in several other studies.

conditions, the data for the experimental conditions were analyzed separately; and comparisons were made with the controls only when they were theoretically interesting.

Persistence of Forewarning and Distraction Effects

The opinion means for each of the experimental conditions are presented in Table 2, where it can be seen that the data generally conform to the predicted pattern.

An analysis of variance with repeated measures indicated a main effect of time of measurement, $F(1, 102) = 39.02$, $p < .01$, with subjects being less favorable after a week had elapsed; and significant interactions appeared between both forewarning, $F(1, 102) = 6.77$, $p < .01$, and distraction, $F(1, 102) = 34.55$, $p < .01$, and time of measurement. Furthermore, the second-order interaction involving all three variables was significant beyond the .01 level, $F(1, 102) = 7.69$.

The directions of the first-order interactions were as predicted: Forewarning initially inhibited opinion change, but this disadvantage vanished over time; and distraction facilitated immediate opinion change, but the initial advantage rapidly dissipated. The significant second-order interaction appears to be due primarily to the fact that in the immediate-measurement condition, the distraction completely nullified the effects of forewarning, yielding a difference of more than 20 points between the distracted and nondistracted subjects' means. This fact is particularly interesting, since it is exactly what would be expected if the major mediating variable was the number of counterarguments produced. That is, if the inhibiting effect of forewarning of persuasive intent is primarily due to the increased production of counterarguments while reading the messages, then, when subjects are distracted from counterarguing, the usual effects produced by forewarning should be nullified.

It is of interest to determine whether the data replicate the earlier finding of a sleeper effect interaction between forewarning and time of opinion measurement when subjects are not distracted. The relevant data are contained in the no-distraction conditions of Table 2 (identical to the earlier study). The immediate effect of forewarning of persuasive intent was to reduce substantially the impact of the messages (Ms = 53.85 vs. 70.77 in the nonforewarned conditions). After a week's delay, however, this initial difference had all but disappeared, with the forewarned group showing an increase of 7.88 points. Planned comparisons (Dunn, 1961) indicated that the interaction and the aforementioned increase were significant beyond the .05 level. Hence, this study showed both relative and absolute sleeper effects for the forewarned groups.

Table 2
Mean Opinion Scores for Each of the Experimental and Control Conditions

Condition	Not forewarned		Forewarned	
	Measurement		Measurement	
	Immediate	Delayed	Immediate	Delayed
No distraction	70.77	63.85	53.85	61.73
Distraction	75.38	59.42	74.42	57.12
Controls	54.42	54.23	47.12	44.52

Note. These means are based on 100-point scales ranging from 0 (Very improbable) to 100 (Very probable). Cell ns = 52.

In regard to the effects of distraction, the data for the no-forewarning conditions, which would be most similar to the typical distraction study, showed the predicted interaction. Distraction facilitated opinion change immediately after reading the communications ($M = 75.38$ for the distracted individuals, compared to 70.77 for those persons in the no-distraction conditions), but after a week, this pattern had reversed, with the nondistracted subjects showing somewhat superior retention of opinion change. This interaction was also significant beyond the .05 level as tested by Dunn's (1961) method.

In summary, there appears to be considerable support for the conjecture that moderate distraction may have a facilitating, but short-lived, effect on opinion change. There was no evidence in the present study that forewarning increased the favorability of sub-

jects' responses to the familiar control issues. In contrast, when only familiar issues were presented, subjects who were forewarned agreed somewhat less strongly with the opinion statements on both the immediate and delayed measurements. There seems to be no ready explanation for the different results obtained with the control issues in the two experiments.

Comprehension

The prediction that forewarning would serve as a discounting cue and lead to a sleeper effect was based on the assumption that it would not interfere with learning of the message content. In contrast, the predictions involving distraction were based in part on the assumption that distraction would interfere with learning and that, consequently, induced change would be quite ephemeral. The mean comprehension scores for each of the experimental conditions are presented in Table 3.

Analysis of variance indicated that the main effect of distraction was significant, $F(1, 102) = 28.33$, $p < .01$, and in the predicted direction. The main effect of forewarning was in the same direction as that obtained in the first study, $F(1, 102) = 2.57$, $p \approx .11$. In contrast to the earlier study, time of measurement had a significant effect, $F(1, 102) = 52.36$, $p < .01$, with subjects remembering less of the messages' contents at the time of delayed measurement. The only other significant effect was the interaction between fore warning and distraction, $F(1, 102) = 4.1$ $p < .05$. There was a greater facilitating e fect of forewarning on learning when subjec were not distracted. Hence, in the prese study, subjects learned significantly less u der conditions of distraction even thoug their opinions were changed much mor These results are quite similar to those ob tained by Insko, Turnbull, and Yande (1974) and Petty et al. (1976), in whos studies, at least under some conditions, di traction interfered with recall but facilitate opinion change. Together, these studies sug gest some limitations of the generalizatio advanced by previous researchers (e.g., Fes inger & Maccoby, 1964; Osterhouse & Broc 1970; Regan & Cheng, 1973) that distractio facilitates opinion change only in cases whe it does not interfere with reception of th message. Naturally, if the interference wit comprehension were severe, the distractio would inhibit opinion change, since one ca only change his or her opinion in the direc tion advocated if he or she knows what tha position is.

Table 3
Mean Comprehension Scores for Each of the Experimental Conditions

Condition	Not forewarned		Forewarned	
	Measurement		Measurement	
	Immediate	Delayed	Immediate	Delayed
No distraction	1.92	1.38	2.19	1.83
Distraction	1.58	1.23	1.65	1.25

Note. These means are based on the number of correct answers to three multiple-choice questions. Cell *ns* = 52.

General Discussion

Effects of Forewarning

Both studies indicated that forewarning o of persuasive intent of a communication pro duced a sleeper effect whereby subjects were more influenced by the message after a week' interval than they were immediately after read ing it. There were at least three reasons fo expecting such a delayed-action effect. The first pertained to the number of counterargu ments evoked by forewarning. It was assumed that if forewarning increased counterarguing less immediate opinion change would result, but that over time, the subjects' reactions would be forgotten or dissociated from the messages, thus allowing the information to have a greater impact. In the first study, forewarned subjects showed a slightly greater tendency toward counterarguing; but the effect fell short of significance. This may have been due, in part, to the insensitivity of the response rating scale employed.

The second reason for expecting a delayed-action effect rested on the assumption that forewarning would increase the subjects' tendencies to derogate the communications. As found in earlier studies (e.g., Dean et al., 1971; Hass & Grady, 1975), subjects rated the messages as less fair and unbiased when forewarned of their persuasive intent. Thus, forewarning apparently served as a discounting cue (much like a negative source), thereby reducing the immediate impact of the communication. However, with the passage of time, subjects tended to forget or dissociate the discounting cue, thus allowing the full impact of the persuasive material to emerge, providing that forewarning did not interfere with comprehension. Consequently, the forewarned subjects would be expected to reach the same level as the nonforewarned group over time. Obviously, whether an absolute increase occurred, as witnessed in the second study, would depend on such factors as the period of time elapsed and the decay rate for the nonforewarned group. This reasoning parallels the original interpretation of the sleeper effect (Hovland et al., 1949), in which it was presumed that the propaganda-type context led to an initial dampening of the film's persuasive impact, but that as this discounting cue was forgotten over time, the subjects accepted the message to a greater extent. Despite the fact that Gillig and Greenwald (1974) have written its obituary, and Capon and Hulbert (1973) have concluded that there is no strong evidence for a generalized sleeper effect, the data in these studies fully supported an opposing stance. Indeed, Gruder et al. (1978) have recently shown that absolute sleeper effects can be obtained when certain conditions are met for strong tests: (a) when a persuasive message has a substantial initial impact on attitudes, (b) when this change is totally inhibited by a discounting cue, (c) when the cue and message are dissociated over time, and (d) when this dissociation occurs quickly enough so that the message still has some impact. The present studies generally would appear to meet these criteria.

As previously mentioned, forewarning may be a better method of studying the sleeper effect than attributing a negative source to a compelling message, since this must often arouse feelings of incredulity, and furthermore, the negative source may be overshadowed by the mention of a number of positive sources in the communication itself. For example, a health message may be attributed to a low-prestige source, such as a high school student, but within the text, various facts may be presented that presumably come from medical journals, learned professors, or prominent physicians. The result could conceivably end in confusion.

The third possibility, that forewarning increases reactance, was not tested in these studies; but again, this view would lead to the predicted delayed-action effect. As Hass and Grady (1975) pointed out, despite the presence of reactance, well-written communications containing compelling arguments often lead to persuasion. The arguments should have greater influence on the subject once the reactance has dissipated.

Actually, all three of the interpretations mentioned above can be viewed as variations of the discounting cue hypothesis, with counterarguments, derogation of source and message, and feelings of reactance each serving as an initial rejection cue.

Effects of Distraction

More rapid decay of opinion change, induced under conditions of distraction, was expected for two reasons. First, distraction has been shown to interfere with comprehension of message content (e.g., Petty et al., 1976; Zimbardo et al., 1970). While correlational studies of memory and persistence have produced somewhat inconsistent results (e.g., Cook & Flay, 1978; Miller & Campbell, 1959; Watts & McGuire, 1964), Cook and Flay point out that experimental manipulations affecting learning have usually influenced persistence of opinion change. Thus, while the immediate effects of distraction may be to increase opinion change (presumably because more is gained from the reduction in counterarguing than is lost through poor comprehension), the long-term prognosis would be a rapid reversion to the level of the nondis-

tracted subjects, if not to a lower level. The data in the present study are consistent with this view, inasmuch as distracted subjects changed more immediately afterward, but not during the delayed measures of opinions; and they scored significantly lower on the comprehension test at both time intervals.

The second reason for expecting the obtained temporal effects depends on postexperimental counterarguing. Although this variable was not assessed in the present study, the fact that distraction completely nullified the immediate effects of forewarning strongly suggests that counterarguing is a major mediating process. After the subject has left the experimental room, it is only reasonable to assume that he or she would be able to think of a greater number of counterarguments to the communications when free to reflect on them without being distracted. This phenomenon should, in turn, serve to move the person's opinion back toward the preexperimental level. It is regrettable that both immediate and delayed counterarguing were not measured in the second study. The rating scale that was used in the first study seemed inadequate, and the more thorough thought-listing procedure (e.g., Brock, 1967) would have been too complicated for our within-subjects design.

The Role of Assumed Reciprocation of Sentiment and Assume Similarity in the Production of Attraction and Agreement Effects in *p-o-x* Triads

Chester A. Insko
University of North Carolina at Chapel Hill

Akanbi Adewole
University of Lagos
Lagos, Nigeria

Two experiments were conducted to explore the adequacy with which balance theory can account for attraction and agreement effects in *p-o-x* triads. The first experiment provided evidence for the importance of assumed reciprocated sentiment in the production of attraction effects, and the second experiment provided evidence for the importance of assumed *p-o* similarity in the production of agreement effects. In addition, both experiments replicated past results concerning the importance of contact for attraction and agreement effects and also found that attraction and agreement effects were more apparent with affective scales (pleasantness and harmony) than with more cognitive scales (expectancy, consistency, and stability). An unexpected finding of the second experiment was that the *p-o* similarity (or social comparison) interpretation of the agreement effect held only for the more cognitive scales.

The present article addresses the general issue of the extent to which balance theory can be elaborated to account for subjects' reactions to hypothetical social situations, like Heider's (1946, 1958) *p-o-x* (or self–other–inanimate object) triad. What is the reason for studying the subjects' reactions to hypothetical social situations? There are at least two possible answers to such a question. One is that such studies are important because they are role-playing simulations of recurrent social situations. (See the Summer, 1977, issue of the *Personality and Social Psychology Bulletin* for a series of articles arguing the pros and cons of such role-playing methodology.) A second, and more compelling, answer to the question asked above relates to the fact that such studies provide an arena for theory development.

There is a tendency to downgrade the importance of research in hypothetical situations because it is "irrelevant." To some extent such a reaction is based on a negative reaction to balance theory, and to some exte it is based on the failure to recognize th from a balance theory perspective, phenom nology is phenomenology—whether it relat to actual or hypothetical situations. There thus the possibility of working out principl that may generally apply. Research on hyp thetical triads can be conceived of as playin a role for the balance theorist that is analo gous to the role played by the Skinner bo for the operant psychologist. The Skinne box, like the hypothetical triad, holds litt intrinsic interest or "relevance." On the oth hand, the Skinner box does provide a situ tion in which variables believed to be theoretical importance can be easily manipu lated and behavior can be easily measured Thus, principles may be worked out that ca be applied to other situations.

Insko, Songer, and McGarvey (1974) hav argued that Heider's *p-o-x* triad can best b conceptualized from the perspective of a three-factor analysis of variance model. The first factor is the positive or negative sign of the *p-o* relation, the second is the positive or negative sign of the *p-x* relation, and the third is the positive or negative sign of the

o-x relation. Within-subjects ratings of the eight possible triads (typically for degree of pleasantness) give seven possible orthogonal effects (three main effects, three double interactions, and a triple interaction). Numerous studies (see Zajonc, 1968, for a review) have found evidence for three of the seven effects. These are the main effect for the *p-o* relation, or attraction effect; the interaction between the *p-x* and *o-x* relations, or agreement effect; and the triple interaction, or three-sign balance effect.[1] The attraction effect is a tendency for subjects to rate *p*-likes-*o* triads as more pleasant than *p*-dislikes-*o* triads. The agreement effect is a tendency for subjects to rate triads in which *p* and *o* both like or both dislike *x* as more pleasant than triads in which *p* and *o* do not agree about *x*. The three-sign balance effect is a tendency for subjects to rate the triads in which the product of the three signs is positive as more pleasant than triads in which the product of the three signs is negative. Stated another way, it is the tendency to rate triads in which *p* likes an *o* with whom there is agreement, or dislikes an *o* with whom there is disagreement, as more pleasant than the triads in which *p* likes an *o* with whom there is disagreement, or dislikes an *o* with whom there is agreement.

It can be argued that attraction and agreement effects are embarrassing to balance theory (cf. Zajonc, 1968). Insko et al. (1974), however, have pointed out that various balance interpretations are possible. These interpretations are based on the general assumption that subjects supply additional cognitive bands beyond the three that are experimentally given. For example, according to Aderman (1969), when subjects consider the *p-o-x* triad, there is a tendency for some of them to think about a specific *o* with whom they interact or have contact. In the language of balance theory, such social interaction is a positive unit relation between *p* and *o*. Insko et al. argued that the addition of this positive unit relation to the *p-o-x* triad (or cycle) produces two additional cycles that provide balance interpretations of attraction and agreement effects.

Counting the research in Insko et al. as one experiment, and including the two experiments reported by McGarvey (1974) as well as an additional unpublished experiment (LaTour et al., Note 1), there are four experiments that have studied the important contact conditions. There are four such conditions: standard (with no mention of contact), future contact, no contact, and breaking contact. According to the unit-relation interpretation, the algebraic magnitudes of the attraction and agreement effects should be as follows: future contact > standard > no contact > breaking contact. Furthermore, the direction of the effects should be positive in the future contact and standard conditions, neither positive nor negative in the no-contact condition, and negative in the breaking-contact condition. With regard to the attraction effect, results have been generally consistent with the predictions given above. The exception is a significant attraction effect in the no-contact condition in one of the four experiments. With regard to the agreement effect, results have been less supportive of the unit-relation interaction. All experiments have obtained the same rank order of conditions: future contact $\simeq$ standard > no contact > breaking contact. Furthermore, three of the four experiments obtained a significant agreement effect in the no-contact condition, and one failed to find a significant negative (or reversed) agreement effect in the breaking contact condition. Clearly the contact interpretation does not adequately account for all of the reliable variance in the agreement effect.

One further complication relates to the fact that some of the studies mentioned above had two future contact conditions: future contact with discussion of *x* and future contact without discussion of *x*. The difference between these two conditions does not obviously reflect either contact or similarity, and the reason for the previously obtained finding of a greater agreement effect with than without discussion (e.g., Insko et al., 1974) is not

[1] Insko, Songer, & McGarvey (1974) refer to attraction effects as "positivity" effects. Since usage seems to be following Zajonc's precedent, we will conform.

clear. Perhaps the explicit elimination of discussion regarding x decreases the importance or weight of the agreement cycle, or perhaps discussion of x produces greater concern with the consequences of disagreement.

As previously indicated, there are several possible interpretations of the attraction effect. One relates to contact, another to reciprocated sentiment. Existing evidence (McGarvey, 1974) indicates that at least some subjects do assume same-sign reciprocation of the *p-o* relation, and research by McGarvey (1974) indicates that a manipulation of reciprocated sentiment alters the magnitude of the attraction effect. Why should this be? Reciprocated positive sentiment produces a balanced cycle, as does also reciprocated negative sentiment. Thus, there would seemingly be no basis for predicting an attraction effect. On the other hand, to the extent that the self, or self-concept, is positively valued, reciprocated positive sentiment produces agreement regarding the worth of the self, and reciprocated negative sentiment produces disagreement regarding the worth of the self. Thus, from the perspective of reciprocated sentiment, the attraction effect is an agreement effect. A crucial issue, therefore, is the extent to which there are balance theory explanations of agreement effects. These explanations may depend on various types of *p-o* unit relations (contact, assumed similarity, etc.).

Experiment 1 was primarily designed to explore the reciprocated sentiment interpretation of attraction effects. Thus, one of the factors was a manipulation of reciprocated sentiment. Beyond this, however, this experiment was also designed to explore the relationship between reciprocated sentiment and other factors of possible theoretical importance. One of these factors relates to the type of rating scale. Existing research by Crockett (1974); Gutman and Knox (1972); Gutman, Knox, and Storm (1974); and Miller and Norman (1976) suggests that pleasantness scales reveal larger attraction effects than do consistency and/or expectancy ratings. Experiment 1 contains a scales factor that includes five different rating scales: pleasantness, harmony, expectancy, consistency, and stability.

It is reasonable to assume that affect is self-related and that an affective rating makes the self more salient than does a more cognitive rating, such as consistency. Pleasure and pain are self-related and cannot exist apart from persons (or organisms). Consistency, however, need not be self-related and certainly can exist apart from persons (e.g., between logical symbols). Thus, to the extent that the attraction effect results from assumed reciprocated sentiment (with its implication of agreement or disagreement regarding the worth of the self), affective ratings will produce a larger attraction effect than will cognitive ratings. In terms of the present design this is a prediction that a contrast effect comparing affective (pleasantness and harmony) scales with cognitive (expectancy, consistency, and stability) scales will be significant.

Recall that McGarvey (1974) found a main effect of reciprocation on attraction using just a pleasantness scale. We predicted that in the present study there would be an interaction between reciprocation and rating scales such that the effect of reciprocation would be more apparent for the affective scales (pleasantness and harmony) than for the relatively more cognitive scales (expectancy, consistency, and stability). The theoretical rationale for this prediction was that reciprocated sentiment produces agreement or disagreement regarding the self-concept, and the affective scales are more directly relevant to cycles including the self-concept as an element (e.g., p interacts with o, p approves of his/her self-concept, o disapproves of p's self-concept). We are assuming that the affective scales are most relevant to cycles that include the self-concept as an element (i.e., cycles in which p's self-evaluation provides one of the signs that determines balance or imbalance in the cycle).

A third factor having a bearing on the reciprocated sentiment interpretation of attraction effects is involvement, or a comparison of *p-o-x* and *q-o-x* triads. With *p-o-x* triads, the subject is told that p, or "I" is the subject himself/herself. With *q-o-x* triads, the subject is asked to assume that q is some person

who is known but has never been met. Subjects are asked to rate the *q-o-x* triads according to how they as *outside observers* would find the situation. In view of the argument detailed above regarding the role of self-relevancy in the production of the attraction effect, high-involvement (*p-o-x*) triads should produce a greater attraction effect than low-involvement (*q-o-x*) triads. However, a study by LaTour et al. (Note 1) did not support this prediction. It is possible, however, that subjects tend to judge *q-o-x* triads by vicariously identifying with *q*. Some evidence for vicarious identification in the context of *p-o-q* (three-person) triads was obtained by Insko et al. (1974). In that study, *o*-to-*q* attraction was found under the special circumstances of *q*-to-*o* same-sign reciprocation. Since same-sign reciprocation also increased the magnitude of *p-q* attraction, it was argued that *o-q* attraction resulted from *p*'s vicarious identification with *o*. Thus, it is plausible that subjects judge the interpersonal situation through at least partial vicarious identification.

We believed it unlikely that vicarious identification would be sufficient to explain all of the subtleties present in *p-o-x* triads. If this is true, it is reasonable to suppose that the prediction given above regarding the greater effect of reciprocation with affective than cognitive scales would be more apparent for *p-o-x* than *q-o-x* triads. This is a triple interaction: Involvement × Reciprocation × Scales. To the extent that this interaction occurs, we would have further support for the supposition that the self-concept is important in an adequate conceptualization of attraction effects.

Finally, we come to the three-sign balance effect. Past results have uniformly indicated a greater effect in the standard condition than in the remaining contact conditions. Such results possibly indicate an attentional shift away from the three-sign balance cycle (that does not include the unit relation) to the attraction and agreement cycles (that do include the unit relation). No further predictions regarding three-sign balance were made.

Experiment 1 contained four between-subjects factors: reciprocation (standard no mention, or explicitly mentioned), scales (pleasantness, harmony, expectancy, consistency, or stability), involvement (*p-o-x* or *q-o-x* triads), and contact (standard, future contact with discussion of *x*, future contact without discussion of *x*, no contact, or breaking contact). The contact factor was included in order to examine the extent to which contact results would generalize across scales.

Experiment 1 did not include a manipulation of triad order. This was not done for two reasons. First, the existing design of four between-subjects factors generates 100 cells, and that is the capacity of the available multivariate analysis of variance program. Second, past research (Insko et al., 1974; McGarvey, 1974) has not found any interactive effects between triad order and other manipulated factors.

Experiment 1

Method

Subjects

The subjects were 1,000 male and female students from the introductory psychology course at the University of North Carolina.

Independent and Dependent Variables

Each subject rated eight triads. These ratings can be conceived of as generating three within-subjects factors: positive or negative sign of the first relation (*p* to *o* or *q* to *o*), positive or negative sign of the second relation (*p* to *x* or *q* to *x*), and positive or negative sign of the third relation (*o* to *x*). These within-subjects factors were used to generate seven orthogonal difference scores corresponding to the main effects and interactions of these factors. Three of these difference scores, the attraction, agreement, and three-sign balance effects, were used as the main dependent variables in a multivariate analysis of variance that included four between-subjects factors. The four between-subjects factors were involvement (*p-o-x* or *q-o-x* triads), reciprocation (standard no mention of reciprocation, or same-sign reciprocation of *p*- or *q*-to-*o* relation), contact (standard, future contact with discussion of *x*, future contact without discussion of *x*, no contact, or breaking contact), and rating scales (pleasantness, expectancy, harmony, stability, or consistency).

Procedure

Subjects were tested in small groups of up to approximately 20 people. In any given group, every

subject was in a different one of the 100 conditions or cells. After subjects had been briefly instructed regarding the procedure for rating each hypothetical situation, they were given a nine-page booklet. Subjects were asked to regard each situation as independent of the others and not to alter a previous response after a page had been turned. It was emphasized that they should rate each of the eight situations and not leave any of the rating scales blank. Remarkably, this instruction was followed by all 1,000 subjects, and no subjects were eliminated from the final sample.

The first page of the booklet contained instructions regarding the experimental procedure and introduced two of the between-subjects factors, involvement and rating scales. For example, the self-involved–consistency instruction was as follows:

> On each of the following eight pages is a description of a situation involving two persons, I and O, and an impersonal object or issue, X. As you read each situation, try and imagine yourself as Person I. Think about what it would be like to be involved in the situation described. Then rate each situation according to the extent to which *you as a person, I,* would find such an interpersonal situation consistent or inconsistent. Make the rating by circling the number on the scale corresponding to how *you as Person I* find the situation. Below is an example of the scale.
>
> Most inconsistent 1 2 3 4 5 6 7 Most consistent

For the self-uninvolved–harmonious-scale condition, the instruction was the following:

> On each of the following eight pages is a description of a situation involving two persons, Q and O, and an impersonal object or issue, X. Imagine that you have never met Q and O but that you know of them and how they feel about X. Rate each situation according to the extent to which *you as an outside observer* would find such an interpersonal situation harmonious or unharmonious. Make the rating by circling the number on the scale that corresponds to how *you as the outside observer* find the situation. Below is an example of the scale.
>
> Most discordant 1 2 3 4 5 6 7 Most harmonious

As previously indicated, five different rating scales were used (most unpleasant – most pleasant, most unexpected – most exepected, most inconsistent – most consistent, most discordant – most harmonious, most changeable – most stable). These rating scales were repeated on each of the eight pages. Each page stated one of the triadic situations, indicated reciprocation (in the appropriate condition), stated assumptions regarding contact (in the nonstandard conditions), and finally gave a rating scale. Here is an example.

> Situation: I like O. I like X. O dislikes X. O likes I (me).
>
> Assume: I and O have not had personal contact in the past and will never have personal contact in the future. However, I and O know enough about each other to form some feelings about each other.
>
> Rating of situation:
>
> Most unpleasant 1 2 3 4 5 6 7 Most pleasant

Reciprocation was manipulated by stating O's feeling for I (or Q) as the same as I (or Q's) feeling for O, or by not mentioning anything about O's feelings. Contact was manipulated by stating (in all but the standard condition) an assumption regarding contact. The assumptions were as follows: I and O have had contact in the past and will have contact in the future and will discuss X; I and O have had personal contact in the past and will have personal contact in the future but will not discuss X; I and O have not had personal contact in the past and will never have personal contact in the future. However, I and O know enough about each other to form some feelings about each other; and I and O have had personal contact in the past but will never have personal contact in the future.

At the conclusion of the experiment, subjects were told about the purposes of the study.

Dependent Variables

It is worth emphasizing that the dependent variables were the seven orthogonal difference scores created by taking the difference between the mean of the ratings for a given four triads and the ratings of the remaining four triads. It is true that the subjects rated the triads for pleasantness, consistency, and so forth. The dependent variables, however, were not pleasantness and consistency, but rather the difference scores. From this perspective the rating scales constituted an independent variable.

Results

Grand Mean Tests

The initial analysis involved a test of the difference from zero for each of the seven orthogonal difference scores (or contrasts). This analysis revealed the usual significant effects for attraction, $F(1, 900) = 179.36$, $p < .01$; agreement, $F(1, 900) = 171.43$, $p < .01$; and three-sign balance, $F(1, 900) = 288.18$, $p < .01$. In addition there was also a significant effect for the second sign (p-x or q-x), $F(1, 900) = 11.36$, $p < .01$. This effect indicates a tendency for the p-likes-x and q-likes-x triads to be rated as more favorable (pleasant, etc.) than the triads in which p dislikes x and q dislikes x. Insko et al. (1974)

Table 1

* $p < .05$. ** $p < .01$.

found a similar effect. A possible balance interpretation of this effect would involve a conceptualization of an x with which p or q has a positive unit relation—a recently purchased bicycle, for example. However, since none of the between-subjects factors were designed to explore this matter, since the effect was small relative to the other three effects, and since the analysis is already complex, reported results will relate solely to the attraction, agreement, and three-sign balance effects.

Multivariate Analysis of Variance

A four-factor multivariate analysis of variance of the attraction, agreement, and three-sign balance effects is presented in Table 1. This analysis revealed significant multivariate Fs for all four main effects, as well as for four of the interactions. Discussion of the significant univariate Fs accompanying the significant multivariate Fs is complex. This material will be presented under three subheadings: rating scales main effect, involvement and reciprocation, and contact.

Rating Scales Main Effect

There was a significant main effect for rating scales. Table 2 contains the marginal means. A contrast comparing the affective scales (pleasantness and harmony) with the more cognitive scales (expectancy, stability, and consistency) was significant for both attraction and agreement. As expected, attraction, $F(1, 900) = 162.12$, $p < .01$, and

Table 2
Rating Scale Means for Experiment 1

Condition	Pleasantness	Harmony	Expectancy	Consistency	Stability
Attraction	5.71**	5.90**	.49	1.02*	.67
Agreement	3.59**	3.84**	.05	.94**	1.78**
Three-sign balance	2.28**	2.08**	1.84**	2.14**	3.92**

Note. Each subject rated eight triads on one of five 7-point scales. These ratings were then converted to attraction, agreement, and three-sign balance scores by taking the difference between the mean of the appropriate four triads and the mean of the remaining four triads. These difference scores (with a possible +7 to −7 range) were then averaged across subjects to give the tabled means.
* $p < .05$, $df = 1, 900$. ** $p < .01$, $df = 1, 900$.

agreement, $F(1, 900) = 89.06$, $p < .01$, effects were greater with the affective scales than with the cognitive.

Grand mean tests were conducted on each of the cell means in Table 2. The significance of these tests of differences from zero is indicated by the asterisks above each mean. All of the means except three (expectancy ratings for attraction and agreement and stability ratings for attraction) differ from zero. The cognitive scales tend to show smaller attraction and agreement effects, with almost no effects at all appearing in ratings of expectancy.

Involvement and Reciprocation

Involvement main effect. There was a significant involvement effect for both attraction and three-sign balance. The marginal means indicated that the attraction effect was greater with self-uninvolved triads (*q-o-x*) than with self-involved (*p-o-x*) triads (M *q-o-x* = 3.52, M *p-o-x* = 2.00), while just the opposite was true for the three-sign balance effect (M *p-o-x* = 2.75, M *q-o-x* = 2.16). This finding suggests a tendency for subjects to react more to the simpler aspects of the triads when they are not personally involved and to react more to the complex aspects of the triads when they are personally involved. Attraction involves one relation, and three-sign balance involves three relations.

Reciprocation main effect. The only significant reciprocation main effect was for attraction. Consistent with McGarvey's (1974) results (which related only to pleasantness ratings of *p-o-x* triads), same-sign reciprocation of the *p-o* or *q-o* relation increased the magnitude of the attraction effect (3.21) over standard (no stated) reciprocation (2.31). As previously indicated, assuming a positively evaluated self-concept, reciprocated positive sentiment produces agreement regarding the self, and reciprocated negative sentiment produces disagreement regarding the self. Thus, from the perspective of reciprocated sentiment the attraction effect can be regarded as an agreement effect.

Reciprocation × Scales interaction. The main effect for reciprocation on attraction was qualified by several interactions, one of which was the Reciprocation × Scales interaction. The cell means and the significance of the grand mean tests for the Reciprocation × Scales × Involvement interaction are given in Table 3. The Reciprocation × Scales interaction for attraction was explored by testing the interaction involving reciprocation and the contrast between affective scales (pleasantness and harmony) and cognitive scales (expectancy, stability, and consistency). The contrast was significant, $F(1, 900) = 23.85$, $p < .01$. The interaction involving this contrast indicates that the main effect for reciprocation is a resultant of the affective scales. The pattern can be seen in Table 3.

An alternative view of this interaction is a qualification of the tendency for affective scales to produce a larger attraction effect than cognitive scales. This aspect of the main effect for rating scales is more apparent

Table 3
Involvement × Reciprocation × Scales Attraction Means for Experiment 1

Involvement and reciprocation	Pleasantness	Harmony	Expectancy	Consistency	Stability
p-o-x triad					
Standard (no mention of) reciprocation	3.28**	2.06*	.60	1.56	−.34
Reciprocation	7.04**	7.74**	.18	−1.22	−.86
q-o-x triad					
Standard (no mention of) reciprocation	4.90**	6.32**	−.46	1.86*	3.32**
Reciprocation	7.60**	7.50**	1.64	1.90*	.58

Note. *p-o-x* triad indicates high personal involvement; *q-o-x* triad indicates low personal involvement.
* $p < .05$, $df = 1, 900$. ** $p < .01$, $df = 1, 900$.

Table 4
Contact Means for Experiment 1

Condition	Standard (no mention of) contact	Future contact with discussion	Future contact without discussion	No contact	Breaking contact
Attraction	2.86*	7.45*	4.20*	3.19*	−3.88*
Agreement	2.75*	4.79*	−.21	2.94*	−.06
Three-Sign Balance	4.58*	2.06*	.86*	3.43*	1.35*

* $p < .01$, $df = 1, 900$.

with stated reciprocation than with standard (no stated) reciprocation. Even with standard reciprocation, however, the effect was still significant, $F(1, 900) = 30.49$, $p < .01$.

The Reciprocation × Scales interaction is consistent with our theoretical argument regarding the effect of reciprocation on attraction. One of the arguments advanced to explain the existence of attraction effects relates to the assumption of reciprocated sentiment. Reciprocated positive sentiment produces agreement regarding the worth of the self, whereas reciprocated negative sentiment produces disagreement regarding the worth of the self. Given that the affective scales are most self-related, it is reasonable that they would most clearly reveal an attraction effect and would also most clearly show an alteration in this effect as a function of the reciprocation manipulation.

Involvement × Reciprocation × Scales interaction. The reasoning outlined above implies that the double interaction pattern shown in Table 3 would reveal itself most clearly in self-involved (p-o-x) triads rather than in self-uninvolved (q-o-x) triads. This, in fact, occurred. The reciprocation main effect was strongest with affective scales and self-involved triads. This interpretation of the Involvement × Reciprocation × Scales interaction was supported by a significant triple interaction involving the affective versus cognitive scales contrast, $F(1, 900) = 5.12$, $p < .05$.

Contact

The remaining results all relate to contact. Consistent with past results, there was a significant contact main effect on attraction, agreement, and three-sign balance. Table 4 contains the marginal means. Four contrasts were planned for both attraction and agreement. For attraction, all contrasts were significant. The first contrast indicated that the three conditions in which contact was either implicitly or explicitly positive showed a greater attraction effect than the two conditions in which contact was either null or negative, $F(1, 900) = 77.12$, $p < .01$. The second contrast indicated that the standard condition, in which contact was implicit, showed a smaller attraction effect than the two future-contact conditions, in which contact was explicit, $F(1, 900) = 281.73$, $p < .01$. The third contrast indicated that attraction was greater with than without discussion, $F(1, 900) = 26.82$, $p < .01$, and the fourth contrast indicated that attraction was algebraically greater in the no-contact condition than in the breaking-contact condition, $F(1, 900) = 130.51$, $p < .01$.

The asterisks in Table 4 indicate the significance for grand mean tests (tests of difference from zero) for each of the cell means. As Table 4 indicates, all of the cell means for attraction were significantly different from zero. Except for the significant mean in the no-contact condition, these results are consistent with the contact interpretation of attraction.

The same planned contrasts that were used for attraction were used for agreement. The first contrast indicated that the three conditions in which contact was either implicitly or explicitly positive showed more agreement than the two conditions in which contact was either null or negative, $F(1, 900)$

Table 5
Contact × Rating Scales Attraction Means for Experiment 1

Contact	Pleasantness	Harmony	Expectancy	Consistency	Stability
Standard (no mention)	7.18**	5.50**	.30	1.70	−.40
Future contact with discussion	7.85**	8.95**	10.20**	6.63**	3.70**
Future contact without discussion	8.00**	7.60**	.30	1.50	3.70**
No contact	7.70**	7.30**	.63	.93	−.60
Breaking contact	−2.10*	.22	−8.93**	−5.55**	−3.05**

* $p < .05$, $df = 1, 900$. ** $p < .01$, $df = 1, 900$.

$= 122.50$, $p < .01$. This contrast was significant in spite of the unexpectedly low mean for future contact without discussion. Furthermore, this unexpectedly low mean appears responsible for the nonsignificance of the second contrast comparing the standard and two future-contact conditions. The third and fourth contrasts revealed the expected results. There was a greater agreement effect with than without discussion, $F(1, 900) = 115.03$, $p < .01$, and agreement was algebraically greater with no contact than with breaking contact, $F(1, 900) = 78.51$, $p < .01$. The grand mean tests indicated that all of the cell means, except the ones for breaking contact and future contact without discussion, were significantly different from zero.

The only planned contrast for three-sign balance was a comparison of the standard condition with the four remaining conditions. Consistent with past results, this contrast was significant, $F(1,900) = 16.1$, $p < .01$. The effect was larger in the standard condition.

As Table 1 indicates, the large contact main effect was qualified by two descriptively smaller interactions: the Reciprocation × Contact interaction for agreement only and the Contact × Rating Scales interaction for attraction and three-sign balance.

The Reciprocation × Contact interaction indicates that the contact predictions for agreement were more strongly supported in the standard condition than in the reciprocation. Theoretically, reciprocation relates most directly to attraction, not agreement. This unexpected interaction may have resulted from an attention shift away from agreement and the bearing of contact on agreement when there was explicit reciprocation.

The potentially most important interaction, Contact × Rating Scales, was not significant for agreement, and the effects for attraction and three-sign balance were not replicated in Experiment 2. The attraction means are contained in Table 5.[2] One of the more interesting aspects of this interaction relates to the means in the no-contact condition. Note that the pleasantness and harmony means in the no-contact condition both differed significantly from zero—contrary to the contact interpretation. Furthermore, they were significantly greater than the means for the cognitive scales, $F(1, 900) = 6.20$, $p < .01$. Such a result makes sense, if it is recalled that it is the affective scales that make the self-concept most salient and thus provide for the production of a positive attraction effect through reciprocated sentiment. The effect was not predicted, but it is consistent with the initially stated theoretical orientation.

Discussion

Experiment 1 had two general purposes, one descriptive and one theoretical. The descriptive purpose was to look simultaneously at the differential effects of five scales (pleasantness, harmony, consistency, expectancy, and stability). Although there is no previous literature for the harmony scale (Heider's term for balance), the existing studies were interpreted as indicating that affective scales (pleasantness and harmony)

[2] An analysis of this interaction by a set of orthogonal contrasts is available from the authors.

would produce larger attraction and agreement effects than cognitive scales (consistency, expectancy, and stability). This, in fact, occurred. Such results may suggest that only the cognitive scales are accurate measures of balance. It should be recognized, however, that all five scales produced significant three-sign balance effects, that the consistency scale produced significant attraction and agreement effects, and that the stability scale produced a significant agreement effect (see Table 2). Only the expectancy scale exhibited a total absence of attraction and agreement effects. On the other hand, the means in the final column in Table 2 descriptively indicate that the expectancy scale produced the smallest three-sign balance effect.

What is the meaning of the term *balance?* Heider (1958) described balanced relations as "harmonious" (p. 180). Clearly he was expressing himself metaphorically. Nonetheless, the metaphor does have an interesting double meaning. For the layman, harmony means affectively pleasing, but for the musician, harmony has more of a cognitive, rational meaning. To the extent that balance has both rational and affective connotations, the term *harmony* may be an appropriate metaphor.

The theoretical purpose of Experiment 1 was to provide support for the reciprocated sentiment interpretation of the attraction effect (the greater pleasantness, consistency, and so forth of the *p*-likes-*o* than the *p*-dislikes-*o* relations). When McGarvey (1974) interviewed a small sample of subjects after they had rated the eight triads, he found that some of them did in fact report that they had considered what the other person might think of them (i.e., considered the nonspecified *o*-to-*p* relation). Furthermore, many of these subjects assumed same-sign reciprocation of sentiment (i.e., *o* likes *p* when *p*-likes-*o* was specified, and *o* dislikes *p* when *p*-dislikes-*o* was specified). McGarvey went on to show that a direct manipulation of reciprocated sentiment increased the magnitude of the attraction effect (on pleasantness ratings).

From a balance theory perspective, the problem is to understand why reciprocated same-sign sentiment should increase the magnitude of the attraction effect. Insofar as attention is directed solely toward the *p*-*o*, *o*-*p* cycle or dyad, both reciprocated liking and reciprocated disliking are balanced. Thus, for this one cycle, there is no way for balance theory to predict McGarvey's results. However, Heider assumed that *p* likes *p*: that the typical individual holds himself/herself in high regard. If the second *p* is regarded as a self-concept with which the first *p* has a positive unit relation, it is balanced for *p* likes *p* (Wiest, 1965). Thus, it follows that reciprocated positive sentiment produces agreement regarding the worth of the self and that reciprocated negative sentiment produces disagreement regarding the worth of the self. This means, of course, that from the perspective of reciprocated sentiment, the attraction effect is an agreement effect. For balance theory the problem is one of whether agreement effects can be reduced to cycles that are consistent with the multiplicative rule. These matters will be discussed in greater detail in the context of Experiment 2, which was more directly concerned with the agreement effect.

Whatever is the correct account of the agreement effect, the discussion above does make obvious that reciprocated sentiment relates directly to self-evaluation. For that reason, the finding in the current study that the main effect of reciprocation on attraction only occurred with more affective scales (pleasantness and harmony) is hardly surprising. The means for this Reciprocation × Scales interaction are contained in Table 3. The occurrence of this interaction provides assurance that the effect of reciprocated sentiment on attraction is indeed mediated by self-relevancy considerations. (This assertion rests on the assumption that pleasure and pain are more obviously self-related than are consistency, stability, and expectancy.) The self-relevancy perspective also provides a partial explanation for the finding that the affective scales produced a larger attraction effect than did the cognitive scales. (Note that this scales effect was present even in the standard condition, in which there was no explicit statement of reciprocation.) To the extent that some subjects assumed reciprocated sentiment with its implications for self-evaluation, it

makes sense that affective scales would be more sensitive to attraction.

One potential problem with this line of argument is the finding of LaTour et al. (Note 1) that the attraction effect in a high-involvement (*p-o-x*) triad was not greater than in a low-involvement (*q-o-x*) triad. The present study, in fact, found that the attraction effect was larger with *q-o-x* than *p-o-x* triads. This result is exactly opposite to what one would expect on the basis of a simple self-relevancy perspective on attraction effects.

It is possible that subjects did not realize that *q* was someone other than themselves. We were, however, sensitive to the problem, and made the instructions as explicit as possible. Subjects were twice instructed to rate the situations according to how "*you as the outside observer*" would find the situation. We initially theorized that subjects judged *q-o-x* triads through partial, vicarious identification. To the extent that such identification does occur, the comparison of *p-o-x* and *q-o-x* triads is less obviously a manipulation of self-involvement. It was further theorized that vicarious identification would not be sufficiently complete to detect all of the subtleties in *p-o-x* triads, and thus the interaction of reciprocation and affective versus cognitive scales should be more apparent with *p-o-x* than with *q-o-x* triads. This triple interaction occurred. The means in Table 3 indicate that the tendency for reciprocation to increase the magnitude of the attraction effect was most apparent with affective scales and *p-o-x* triads. The occurrence of this triple interaction is the heart of the present study and strongly implies that some of the variance in attraction effects is mediated by self-relevancy considerations.

A further finding that in retrospect appears consistent with the argument detailed above is that the three-sign balance effect was larger with *p-o-x* than with *q-o-x* triads. The attraction effect was larger with *q-o-x* triads, but the three-sign balance effect was larger with *p-o-x* triads. The vicarious identification tendency does rather well in reproducing the simpler effects, but less well in reproducing the more complex effects. (Attraction is a main effect and three-sign balance a triple interaction.)

The remaining results all related to contact. Past studies of these matters had used only pleasantness and expectancy scales (LaTour et al., Note 1) or only pleasantness scales (Aderman, 1969; Insko et al., 1974; McGarvey, 1974). The present results add generality to the contact-cycle analysis of Insko et al. Despite the fact that half of the cells involved an explicit statement of reciprocation that appears to have partially distracted attention from the contact cycles, the results by and large were consistent with past results. As the means in Table 4 indicate, attraction was maximized by the explicit statement of future contact and was reversed, or negative, in the breaking-contact condition. The major finding that was *not* consistent with the contact-cycle analysis was the fact that the no-contact mean of 3.19 (see Table 4) was significantly greater than zero. According to the contact-cycle analysis, this mean should be within error variance of zero. This theoretical analysis relates most directly to *p-o-x* triads in which there is no stated reciprocation. However, even within this condition, the mean of 2.42 still differed from zero, $F(1, 900) = 5.25$, $p < .01$.

A further possibility is that some of the subjects in the standard-reciprocation–no-contact condition assumed reciprocation that produced an attraction effect. Some circumstantial evidence for this possibility comes from the finding that the affective scales (pleasantness and harmony) were responsible for the attraction effect under no contact. This pattern can be clearly seen along the no-contact row of Table 5.

Experiment 2

The general purpose of the present line of research was to examine the extent to which balance theory is capable of providing interpretations of attraction and agreement effects in the perception of hypothetical situations. Experiment 1 provided support for the hypothesis that contact and cycles containing the contact unit relation can account for at least some of the variance. Previous research (Aderman, 1969; Insko et al., 1974; McGarvey, 1974; LaTour et al., Note 1) has consistently demonstrated the importance of contact when

subjects respond on pleasantness scales. Experiment 1 found that although there were differences among various scales (see Table 5), the effects of contact were evident for all scales. Experiment 1 went further and produced evidence that reciprocated sentiment and self-relevancy considerations were also important in explaining attraction effects. The theoretical account provides a possible explanation for the fact that affective scales revealed a larger attraction effect than did more cognitive scales.

The major remaining problem relates not to attraction, but to agreement. The above-cited studies, and also Experiment 1, all found that the agreement effect was altered in theoretically predictable ways by the manipulation of contact. In general, however, the contact predictions for the agreement effect have been confirmed less frequently than has been the case for the attraction effect. Experiment 1 is a case in point. Note that the contact prediction of a reversed (negative) attraction effect with the breaking-contact condition was supported, but the analogous prediction of a reversed agreement effect with breaking contact was not supported. The agreement mean in this condition was −.06 (see Table 4). Even within the more appropriate standard-reciprocation condition, the breaking-contact mean was −.73— still not significantly less than zero. Another way of making this point is to note that the contact F for agreement (37.68) was descriptively smaller than the contact F for attraction (80.39).

It is clear that contact does affect agreement. It is, of course, intuitively compelling that disagreement with an *o* with whom there is direct contact has more impact than disagreement with an *o* with whom there is no direct contact. Milgram's (1965) "immediacy"-of-the-victim finding is a possible illustration of an analogous effect. On the other hand, it is also intuitively compelling that disagreement has an impact even when there is no contact with *o*. Why is this? Experiment 2 was designed to explore one possible explanation.

The best known theory of social influence is, of course, social comparison theory (Festinger, 1954). Social comparison posits a self-evaluative drive that results in a motivational force to validate opinions. Validation of opinions (or more specifically, nonverifiable opinion) is sought through agreement with others. Thus, social comparison theory provides a possible explanation of the agreement effect.

Acceptance of the social comparison theory explanation of agreement effects would involve an admission that balance theory could not account for the no-contact variance in the agreement effect. This would not mean that balance theory was incorrect; but it would mean that balance theory was of more limited generality. Balance theory explanations proceed by identifying some implicit aspect of *p*'s phenomenology that can be reduced to a balanced cycle. The theory itself does not specify the important aspect of the phenomenology, and the subject himself/herself may not be explicitly aware of the process that is causally important (cf. Nisbett & Wilson, 1977). This matter is illustrated by previously obtained results regarding contact. When McGarvey interviewed a sample of 18 subjects after they had rated the standard eight triads for pleasantness, he found that 13 of the subjects reported thinking about an *o* with whom there was interaction. Heider's (1958) statement of balance theory does not indicate that subjects will so concretize the situation, and it is rather doubtful that subjects recognized the importance of assumed contact in the production of attraction and agreement effects (although McGarvey did not specifically ask about this).

The current challenge is to identify some implicit aspect of *p*'s phenomenology. Examination of McGarvey's interview results indicates that in 8 out of 18 instances, the subjects imagined *o* to be a specific acquaintance, usually a friend or a peer. It is interesting that these subjects conceptualized *o* as someone who was *similar*—similar in cultural experience and in reasoning capacity. They did not conceptualize *o* as a "man from Mars," a member of another culture or subculture, a resident of a mental institution, or a child. From a balance theory perspective, similarity is a unit relation. Therefore, even under conditions of no contact, there would be an agreement cycle—*p* agrees with a

similar *o* or *p* disagrees with a similar *o*—and also an attraction cycle—*p* likes a similar *o* or *p* dislikes a dissimilar *o*. The analysis parallels Insko et al.'s (1974, p. 56) cycles interpretation of contact, except that in this instance the unit relation involves similarity and not contact.

It is intriguing that social comparison theory appears to take an analogous position regarding similarity. According to Festinger (1954), "a person who believes that Negroes are the intellectual equals of whites does not evaluate his opinions by comparison with the opinion of a person who belongs to some very anti-Negro group" (p. 21). Why does social comparison theory make this assumption? Social comparison theory itself does not answer this question. Festinger appears to have intuited a balance implication without being explicit about it.

The manipulation of similarity in Experiment 2 had three levels: a standard condition (with no mention of similarity), a similar condition ("O generally has interests and attitudes similar to yours"), and a dissimilar condition ("O generally has interests and attitudes dissimilar to yours"). In addition, there were manipulations of scales (pleasantness, harmony, consistency, expectancy, and stability) and contact (standard, future contact, no contact, and breaking contact). Since the theoretical import of future contact with and without discussion of *x* is not clear, reference to discussion of *x* was simply omitted. Altogether the design involved 60 between-subjects cells ($3 \times 5 \times 4$).

The scales factor was included to gain some information regarding the generality of the similarity manipulation, and the contact factor was included to examine the extent to which similarity produced effects beyond those resulting from positive, absent, or negative contact. The factorial combinations produced by the present design present a theoretical dilemma regarding the effects of contact across the levels of similarity. It is possible that the effects of contact may summate (or average) with those of similarity, or that the effects of contact will be more apparent with standard similarity (when there is no explicit mention of similarity). The latter possibility could be the result of attention shifts and/or of information overload.

Previous research has obtained results that appear to be the result of attention shifts. First, Experiment 1, in agreement with previous research (Aderman, 1969; Insko et al., 1974; McGarvey, 1974; LaTour et al., Note 1), found that the explicit mention of contact reduced the magnitude of the three-sign balance effect from its magnitude in the standard condition (with no mention of contact). Second, Experiment 1 found that the explicit statement of reciprocation reduced the magnitude of the agreement effect from its magnitude in the standard-reciprocation condition in which there was no mention of reciprocation. Third, manipulations of triad order by Insko et al., and also McGarvey, found that the magnitude of the three-sign balance effect was greater if the first triad was three-sign imbalanced (and thus more atypical and attention getting) rather than three-sign balanced.

Method

Subjects

The subjects were 600 male and female students from the introductory psychology course at the University of North Carolina.

Independent and Dependent Variables

As in Experiment 1, each subject rated the standard eight triads, and these ratings were used to generate seven orthogonal effects. The major analyses, however, concerned the attraction, agreement, and three-sign balance effects.

There were three between-subjects factors: similarity (standard, similar, or dissimilar), contact (standard, future contact, no contact, or breaking contact), and rating scales (pleasantness, expectancy, harmony, stability, or consistency).[3] The basic design involved 60 between-subjects cells and three dependent variables with 10 subjects per cell.

Procedure

The procedure closely paralleled that of Experiment 1. Subjects were tested in groups of approxi-

[3] Through an oversight the negative endpoint of the stability scale was changed from "Most changeable" to "Most unstable," and the negative endpoint of the harmony scale was changed from "Most discordant" to "Most unharmonious."

Table 6
Multivariate Analysis of Variance for Experiment 2

Source	Attraction F	Agreement F	Three-sign balance F	Multivariate F
Similarity (S)	6.65**	21.60**	3.18*	5.15**
Contact (C)	65.21**	9.50**	5.99**	11.05**
Scales (L)	17.93**	24.19**	1.50	6.40**
S × C	3.17*	2.45*	1.67	1.92**
S × L	4.10**	2.20*	1.21	1.96**
C × L	1.24	.52	1.06	1.20
S × C × L	.84	.75	.80	1.29

* $p < .05$. ** $p < .01$.

mately 25 people, and no two subjects in any group were in the same experimental condition. Each subject received a nine-page booklet, the first page of which gave general instructions and the remaining pages of which listed each of the eight triads (one per page), along with a statement of one or more assumptions and a rating scale. The similarity assumptions were stated as follows.

Assume: O generally has interests and attitudes similar to yours.

Or

Assume: O generally has interests and attitudes dissimilar to yours.

As in Experiment 1, no subjects failed to rate all eight triads, and thus no subjects were eliminated from the analysis.

Results

Grand Mean Tests

Grand mean tests of the seven analysis of variance contrasts for the eight triads revealed the usual attraction, $F(1, 540) = 110.88$, $p < .01$; agreement, $F(1, 540) = 149.80$, $p < .01$; and three-sign balance effects, $F(1, 540) = 252.67$, $p < .01$. This analysis also found an unexpected First × Second Sign interaction, $F(1, 540) = 6.70$, $p < .01$. Triads in which the p-o and p-x relation were of the same sign were rated higher than triads in which these two relations were of unlike sign. Subsequent analyses focused on the descriptively larger attraction, agreement, and three-sign balance effects.

Multivariate Analysis of Variance

A three-factor multivariate analysis of variance of the attraction, agreement, and three-sign balance effects is presented in Table 6. This analysis revealed significant multivariate Fs for all three main effects, as well as for two of the interactions. Since both of the interactions involve similarity, we will begin with a description of the main effects for rating scales and contact.

Rating Scales Main Effect

There was a significant rating scales main effect for both attraction and agreement. Table 7 contains the marginal means. A contrast comparison of the affective scales (pleasantness and harmony) with the more cognitive scales (expectancy, stability, and consistency) was significant for both attraction, $F(1, 540) = 60.16$, $p < .01$, and agreement, $F(1, 540) = 71.50$, $p < .01$, indicating a greater effect with the affective scales and replicating a similar finding in Experiment 1.

A second contrast comparing expectancy and consistency scales with the stability scale indicated a greater effect with stability for both attraction, $F(1, 540) = 15.66$, $p < .01$, and agreement, $F(1, 540) = 25.10$, $p < .01$. This contrast, which was significant for agreement but not attraction in Experiment 1, possibly means that stability has a more affective connotation than do expectancy and stability.

Grand mean tests were conducted on each of the cell means in Table 7, which also includes the means for three-sign balance. Except for the failure of consistency to reveal significant attraction and agreement effects and the presence of a significant attraction effect for stability, the results replicated the findings of Experiment 1.

Table 7
Rating Scale Means for Experiment 2

Condition	Pleasantness	Harmony	Expectancy	Consistency	Stability
Attraction	4.34**	5.52**	−.26	.78	3.02*
Agreement	4.21**	4.44**	−.74	1.24	2.97*
Three-sign balance	3.44**	2.39*	2.79*	3.31**	2.40*

* $p < .05$, $df = 1, 540$. ** $p < .01$, $df = 1, 540$.

Contact Main Effect

In agreement with Experiment 1 and all past results, there was a significant contact main effect on attraction, agreement, and three-sign balance. Table 8 contains the marginal means. Three contrasts were planned for attraction and agreement. First, attraction was greater in the standard and future-contact conditions than in the no-contact and breaking-contact conditions, $F(1, 540) = 55.54$, $p < .01$, as was also agreement, $F(1, 540) = 18.57$, $p < .01$. Second, attraction was greater in the future-contact than in the standard condition, $F(1, 540) = 84.23$, $p < .01$, but the contrast was not significant for agreement. Third, attraction was greater with no contact than with breaking contact, $F(1, 540) = 55.86$, $p < .01$, as was also agreement, $F(1, 540) = 7.83$, $p < .01$.

The asterisks in Table 8 indicate the significance of the grand mean tests (tests of differences from zero) for each of the cell means. The failure of the attraction mean in the standard condition to reach significance is inconsistent with the results of Experiment 1 (see Table 4) and is not in agreement with the general assumption that some subjects in a standard condition implicitly assume contact. As is indicated below, however, the standard contact mean was significantly greater than zero within the standard similarity condition (see Table 10).

The only planned contrast for three-sign balance was a comparison of the standard condition with the four remaining conditions. In agreement with Experiment 1, the contrast was significant, $F(1, 560) = 10.24$, $p < .01$.

Similarity Main Effect

There was a significant similarity main effect for attraction, agreement, and three-sign balance; the marginal means for attraction and agreement are in the right-hand column of Table 9. A contrast of the standard condition (with implicit similarity) and similar condition with the dissimilar condition was significant for both attraction, $F(1, 540) = 13.25$, $p < .01$, and agreement, $F(1, 540) = 27.69$, $p < .01$. A second contrast of the standard and similar conditions was significant for agreement only, $F(1, 540) = 15.51$, $p < .01$. According to the similarity interpretation of attraction and agreement, all four of these contrasts should have been significant. The agreement results were more in accord with prediction than were the attraction results (in contrast to the contact results, in which the opposite occurred). Grand mean tests (see

Table 8
Contact Means for Experiment 2

Condition	Standard (no mention of) contact	Future contact	No contact	Breaking contact
Attraction	1.27	7.88**	3.47**	−1.91*
Agreement	2.87*	3.68**	2.35*	.78
Three-sign balance	3.65**	2.23*	3.60**	1.99*

* $p < .05$, $df = 1, 540$. ** $p < .01$, $df = 1, 540$.

Table 9
Similarity × Rating Scales Means

Condition and similarity	Pleasantness	Harmony	Expectancy	Consistency	Stability	Marginal
Attraction						
Standard (no mention)	2.88*	6.08**	.85	2.60*	3.93**	3.27**
Similarity	4.00**	5.60**	−.40	3.05**	4.78**	3.41**
Dissimilarity	6.15**	4.90**	−1.23	−3.33**	.35	1.37
Agreement						
Standard (no mention)	3.53**	4.63**	−.60	1.50	1.98*	2.21*
Similarity	5.00**	5.00**	1.00	4.00**	5.58**	4.12**
Dissimilarity	4.10**	3.70**	−2.63**	−1.78*	1.35	.95

* $p < .05$, $df = 1, 540$. ** $p < .01$, $df = 1, 540$.

Table 9) indicated that significant attraction and agreement effects occurred in all but the dissimilar condition. According to the similarity interpretation, the attraction and agreement effects should have been negative in the dissimilar condition. In reality, of course, contact and reciprocation also have some bearing on these means.

The results for three-sign balance indicated that only the first contrast was significant, $F(1, 540) = 5.66$, $p < .05$. Three-sign balance was greater in the standard and similar conditions than in the dissimilar condition.

Similarity × Rating Scales Interaction

Unfortunately for the sake of both initial prediction and simplicity of discussion, the main effect for similarity mentioned above was qualified by a Similarity × Rating Scales interaction. The attraction and agreement means are contained in Table 9. A series of contrasts was calculated to explore this pattern of results.[4] These contrasts indicated that greater attraction and agreement effects with the standard and similar conditions than with the dissimilar condition were only found for the cognitive scales (expectancy, consistency, and stability). For attraction the effect for pleasantness and harmony was even in the wrong direction, although only slightly. For agreement, the effect was in predicted direction, although not significantly so. These results indicate that the social comparison theory perspective is only supported by the more cognitive scales. Put less technically, the subjects indicated that they regarded agreement with a dissimilar other as inconsistent but not unpleasant.

Similarity × Contact Interaction

There was a significant Similarity × Contact interaction for both attraction and agreement. As the means in Table 10 indicate, the interaction implies that the contact predictions were more strongly supported in the standard-similarity condition. Such a result is in agreement with the anticipation that the factorial combination of similarity and contact might result in attention shifts and/or information overload. It is, furthermore, reassuring to find that the attraction effect with standard contact is significantly greater than zero when there is standard similarity. Across all levels of similarity the standard contact mean was not significantly greater than zero (see Table 8).

Scales Within the No-Contact Condition

One further finding should be mentioned. This finding is relevant to the argument that assumed reciprocation and self-relevancy considerations are important in accounting for attraction variance in the no-contact condition. To the extent that self-relevancy con-

[4] A detailed summary of these analyses is available from the first author.

Table 10
Similarity × Contact Means

Condition and similarity	Standard (no mention of) contact	Future contact	No contact	Breaking contact
Attraction				
Standard (no mention)	2.76*	9.92**	4.12**	−3.74**
Similarity	1.48	7.36**	4.04**	.74
Dissimilarity	−.42	6.36*	2.26*	−2.72*
Agreement				
Standard (no mention)	3.96**	3.32**	2.04*	−.50
Similarity	4.80**	5.56**	3.56**	2.54*
Dissimilarity	−.14	2.16*	1.46	.32

* $p < .05$, $df = 1, 540$. ** $p < .01$, $df = 1, 540$.

siderations are important in the no-contact condition, the affective scales should produce greater attraction than the more cognitive scales. This happened in Experiment 1 (see Table 5). A planned test of the same contrast in Experiment 2 was also significant, $F(1, 540) = 35.60$, $p < .01$. Mean attraction effects for the pleasantness, harmony, expectancy, consistency, and stability scales were 4.47, 8.60, −.03, 1.53, and 2.80, respectively.

Postexperimental Questionnaire

Finally, we should like to mention that Experiment 2 also collected some self-report data—data that will only be briefly described. Since the one variable that appears to be most consistently important in a balance account of attraction and agreement effects is contact, and since McGarvey's informal postexperimental interviews on this matter were only done with 18 subjects, we were interested in collecting data from a somewhat larger sample. The first question, which was asked only in the standard contact condition, inquired whether the subjects thought of a specific *o* (another person) with whom they had contact. The results were even more striking than McGarvey's since 136 of 150 subjects (90.7%) answered in the affirmative. The second question, which was also asked in the nonstandard conditions, inquired about the time duration of the contact. All but one subject in the standard condition specified present contact. In the nonstandard conditions, the question constituted a manipulation check on past and future contact and overwhelmingly yielded the expected results.

The final set of questions was directed at a matter with which we were most concerned. This is the potential criticism that the previously obtained contact results were an artifact of choice. Perhaps when subjects were told to assume no more contact or continued contact in the future they imagined that this change was the result of their own free choice. A set of questions designed to get at this problem revealed that some subjects imagined that their contact was the result of *p*'s choice; some, of *o*'s choice; some, of mutual choices; some, of no-choice circumstances; and some, of a combination of choice and circumstances. Since the modal response category was "circumstances," this category was compared with all of the other choice categories. Except in two instances, this analysis revealed no significant effects. In the future-contact condition, the agreement effect was greater for no-choice than for choice subjects; and in the breaking-contact condition, the attraction effect was more negative for no-choice than choice subjects. In general, the results do not seem to indicate that the usual contact results are an artifact of choice.

Discussion

Experiment 2 generally replicated the Experiment 1 results relating to rating scales and contact. The two experiments agreed in the major finding that the affective scales (pleasantness and harmony) produced larger

attraction and agreement effects than did the cognitive scales (expectancy, consistency, and stability). It is also interesting that in neither Experiment 1 nor Experiment 2 did expectancy ratings reveal significant attraction or agreement effects. The means in Experiment 2 are, in fact, slightly negative. LaTour et al. (Note 1) also did not find that expectancy ratings produced significant attraction or agreement effects. All three experiments found that expectancy ratings did not reveal significant attraction or agreement effects, but did reveal significant three-sign balance effects. These results possibly indicate that when subjects make expectancy judgments, they rely to a great extent on the relative frequencies of past social experiences (i.e., they rely on something analogous to the long-run relative frequency interpretation of probability). From this perspective, subjects do not regard *p*-dislikes-*o* or *p*-disagrees-with-*o* situations as infrequent. On the other hand, three-sign imbalanced situations in which *p* likes someone and disagrees with that person or dislikes someone and agrees with him/her may have a relatively low frequency of past occurrence —possibly because past group relationships tend to be ones in which there is both attraction and agreement (cf. Newcomb, 1978).

The results for contact were generally in accord with the findings of Experiment 1. It is again apparent that more of the contact predictions were supported for attraction than for agreement. In view of the fact that the explicit mention of similarity and/or dissimilarity appeared to lessen the magnitudes of some of the predicted contact effects, this general replication of basic results is gratifying.

The main focus of Experiment 2 was on the anticipated effect of similarity on attraction and agreement. Experiment 2 can be regarded as a test of the social comparison theory perspective on agreement and attraction effects. This perspective is that we seek agreement with and are attracted to similar others. The anticipated main effect of similarity on both attraction and agreement occurred. Both attraction and agreement effects were greater in the standard and similar conditions than in the dissimilar condition. Furthermore, the agreement effect was greater in the similar condition than in the standard condition. Beyond this, however, the attraction and agreement effects were not significantly less than zero in the dissimilar condition, and, most important of all, the main effect of similarity was qualified by the rating scales factor. With the affective scales, the manipulation of similarity had no significant effect on either attraction or agreement (see Table 9). Agreement with similar and dissimilar others was equally pleasant, but not equally consistent. Although this finding is intuitively plausible, it was not anticipated. There does not seem to be anything in social comparison theory that would have indicated such results. Indeed, the basic assumption of a drive for self-evaluation might be interpreted as implying a greater effect on the affective than on the cognitive scales—certainly not a lesser effect.

From the perspective of our initial expectations, Experiment 2 was a qualified success. Some additional agreement variance, beyond that explained by contact, was accounted for, but there was obviously unexplained variance, particularly on the affective scales. The problem becomes acute when it is recognized that it was the affective scales that produced the most agreement variance. Also it is important to note that a balance account of the reciprocated sentiment results for attraction is dependent on the adequacy with which balance theory can account for agreement variance. At the present time it is apparent that the balance theory is better able to account for variance on the cognitive scales than for variance on the affective scales.

We regard the results of the two experiments as sufficiently encouraging to warrant continued investigation of the possibility that balance theory can account for the reliable variance in the phenomenology of hypothetical social situations. As previously indicated, the rationale for studying hypothetical social situations is not necessarily to learn about actual social situations. Although the phenomenology of actual social situations may bear some resemblance to the phenomenology of hypothetical social situations (cf. Sampson & Insko, 1964, for a study of nonhypothetical

p-o-x triads), there are some important differences. At the very least the phenomenology of actual situations will be more complex and span a greater period of time. Hypothetical social situations are studied because the ease of manipulating variables makes these situations a convenient arena for testing specific balance hypotheses. Balance theory should be able to account for certain aspects of human thought, whatever their basis in reality.

Editors Named for New *Journal of Personality and Social Psychology*

The Publications and Communications Board has named Melvin Manis, Ivan D. Steiner, and Robert Hogan to edit the *Journal of Personality and Social Psychology* (JPSP), which will appear in a new format in January 1980. The affiliations of the new editors are, respectively, University of Michigan and Veteran's Hospital, Ann Arbor; University of Massachusetts; and Johns Hopkins University. Manis will edit the section on ATTITUDES AND SOCIAL COGNITION, Steiner the section on INTERPERSONAL RELATIONS AND GROUP PROCESSES, and Hogan the section on PERSONALITY PROCESSES AND INDIVIDUAL DIFFERENCES.

An announcement on the restructuring of JPSP appeared on p. 668 of the June 1978 issue of JPSP. As indicated at that time, the three editors will work independently with separate groups of advisory editors. Their acceptances will appear as distinct sections in monthly issues of JPSP. Detailed descriptions of each section's coverage appear on pages 468–469 of the March issue of JPSP.

Authors should submit manuscripts to the appropriate section editor as follows:

ATTITUDES AND SOCIAL COGNITION

April 1 through June 15:

Melvin Manis
c/o Anita DeVivo
Suite 700
1400 North Uhle Street
Arlington, Virginia 22201

After June 15:

Melvin Manis
Research Center for Group Dynamics
Institute for Social Research
University of Michigan
Ann Arbor, Michigan 48104

INTERPERSONAL RELATIONS AND GROUP PROCESSES

Ivan D. Steiner
Department of Psychology
University of Massachusetts

APA EMPLOYMENT BULLETIN

Possibly your key to greater career opportunities.

Each month 125 to 150 position openings are listed by geographical area and employment field for psychologists with a minimum of a Master's degree. Members may also publish availability notices. Coded identification numbers assure confidentiality. Ideal for employers, students, and Master's and Ph.D graduates.

A one year subscription is as little as $9.00 for members, $16.00 for nonmembers. If you're in a hurry, First Class delivery is available for an additional $4.00.

For more information, contact:

POSITIVE SOCIAL BEHAVIOR AND MORALITY VOLUME 1
SOCIAL AND PERSONAL INFLUENCES

By ERVIN STAUB

What leads human beings to helping, generosity, cooperation, sensitivity to others, and the reciprocation of others' kindness? What values and beliefs guide them to help others in need, to extend effort to increase others' well-being, to try to do what is "right" in their conduct toward others? When do they experience sympathy, empathy, and other emotions that tie them to other people and lead to altruistic acts? What influences positive behavior toward strangers, friends and intimates, members of ingroups and outgroups? This book concerns itself with these questions. It examines and integrates the extensive research and lively theorizing that exists about how personal characteristics and the nature of specific circumstances and of the surrounding social world affect positive conduct. It provides a new theoretical conception and suggests new areas for future research.

1978, 490 pp., $19.50 ISBN: 0-12-663101-8

VOLUME 2
SOCIALIZATION AND DEVELOPMENT

By ERVIN STAUB

It is of great importance for the welfare of individual human beings and for the harmonious functioning of society that people engage in conduct that benefits others—that they help others in need and attempt to contribute to others' welfare. The tendency to behave positively, and the personal characteristics that make positive behavior more (or less) likely develop through socialization, through the influence of peers, and through the child's varied experiences are investigated in this book. How do these influences, together with the nature of the social world, affect children's awareness of and concern with "right" and "wrong"? How are children's values and beliefs, their sense of connectedness to other human beings, their capacity for empathy, sympathy, and identification with others affected? By what principles of learning and development are the varied influences incorporated into the child's personality and behavior?

This book explores and integrates the extensive research and theorizing in these domains, identifies previously unrecognized or unexplored influences on children's positive tendencies, and points to future directions for the field. It suggests to all those concerned with the optimal social development of children, ways of promoting a positive orientation towards other human beings and positive social behavior.

Volume I and II of *Positive Social Behavior and Morality* are related and enlarge upon each other. The material in them is so organized that each can be meaningfully read independently, and each represents an independent whole.

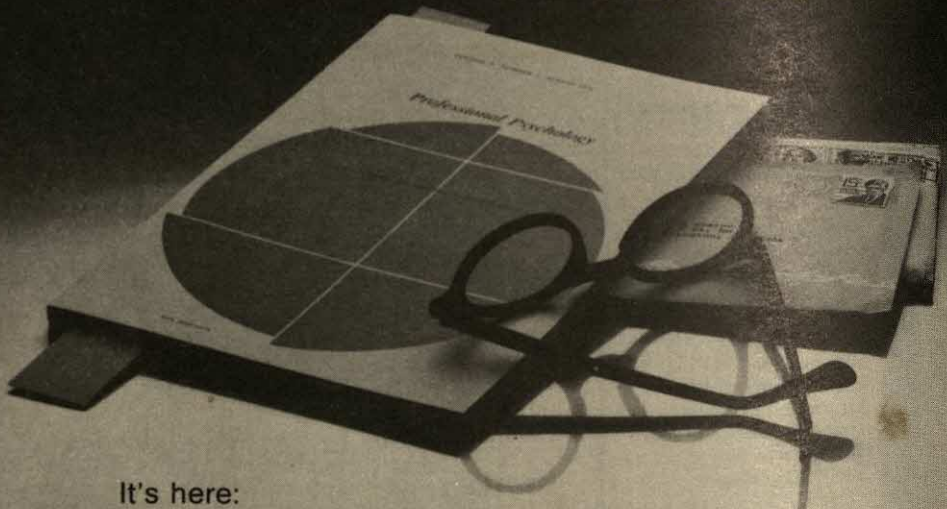
NOW: INFORMATION ABOUT THE LAW AND PSYCHOLOGY.



It's here:
Law and Professional Psychology. This special August 1978 issue of **Professional Psychology** brings you thirteen original articles full of fresh thought and constructive recommendations on the issues that vitally affect your day-to-day practice. You'll find precautions you may take to protect yourself as a professional and a plan for improving investigations of malpractice claims. Expert witness testimony, jury selection, civil commitment, confidentiality and privilege, minor's consent to treatment, and the use of psychological devices are critically examined.

Send your order today. And soon you'll receive this special issue.

Single copies of the issue are available for $5 each. All orders $25 or less must be prepaid. Make and send checks payable to:

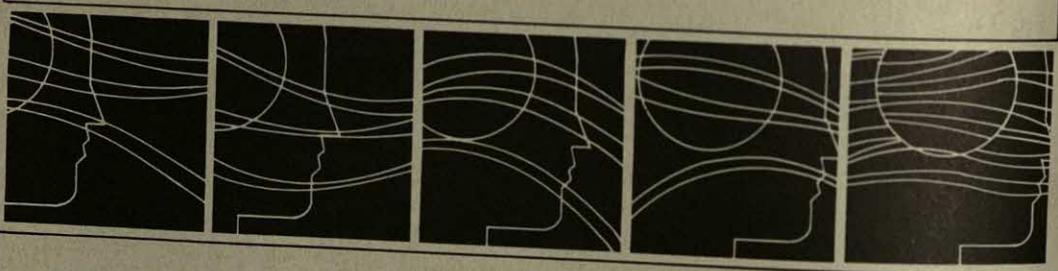
Resources in Environment and Behavior



NEW FROM APA IN 1979

An invaluable sourcebook for students, instructors, and researchers in the new field of environment and behavior. This solid reference includes:

- Overview and history of this emerging field
- Graduate programs—both formal and informal
- Teaching innovations introduced in the United States, Canada, and Great Britain
- Funding sources
- Career opportunities
- Directory of key individuals currently working in the field
- Annotated bibliography
- Listing of relevant journals

Resources in Environment and Behavior is available from the American Psychological Association for $10 (soft cover only). To order, make your check payable to APA.

The Journal of Personality and Social Psychology publishes original reports of research, methodology, theory, criticism, and literature review in the fields of personality and social psychology of normal processes and populations. Submitted manuscripts should delineate an important question and provide a clear answer to it. In the case of research reports, this will often require demonstration that the reported results are generalizable beyond a single research setting. Consult the editorial in the January 1976 issue (Vol. 33, pp. 1–7) for a detailed statement of policies and instructions to authors.

Manuscripts: Submit manuscripts in quadruplicate, prepared according to the *Publication Manual of the American Psychological Association* (2nd ed.). Copies should be highly legible and will not be returned to authors unless they are original typewritten copies. Mail manuscripts according to instructions on p. 809 of the May issue.

Required supplementary information: Manuscripts cannot be reviewed for publication unless the author provides supplementary information in the following categories: (a) a cover letter that indicates the relation (or the lack of relation) of the submitted manuscript to other papers by the same author(s) that are currently submitted, in press, or recently published; (b) one copy of each such related paper; (c) one copy of a statement of the procedures of the research reported in the submitted manuscript in sufficient detail to serve as a guide for conduct of an exact replication; and (d) one copy of the summary tables (e.g., correlation tables, analysis of variance summaries) for the *major* analyses reported. If it appears that the supplementary materials in categories (c) or (d) might be bulky, the author should exercise judgment and restaint in selecting what to send. It is not necessary to send supplementary material that repeats verbatim manuscript content.

After a manuscript is accepted, authors will be expected to provide assurance that their data are available in unanalyzed form for reanalyses by other investigators and that their research procedures were consistent with the American Psychological Association's published principles of research ethics, except insofar as may be detailed otherwise in the manuscript.

Copyright and Permission: All rights reserved. Written permission must be obtained from the American Psychological Association for copying or reprinting text of more than 500 words, tables, or figures. Permission is normally granted contingent upon like permission of the author, inclusion of the APA copyright notice on the first page of reproduced material, and payment of a fee of $10 per page, table, or figure. Abstracting is permitted with credit to the source. Permissions and fees are waived for authors who wish to reproduce their own material for personal use; fees only are waived for authors who wish to use their own material commercially. Permission and fees are waived for the photocopying of isolated articles for nonprofit classroom or library reserve use by instructors and educational institutions. Libraries are permitted to photocopy beyond the limits of U.S. copyright law: (1) those post-1977 articles with a code at the bottom of the first page, provided the per-copy fee indicated in the code is paid through the Copyright Clearance Center, P.O. Box 765, Schenectady, NY 12301; (2) pre-1978 articles, provided that the per-copy fee stated in the Publishers' Fee List is paid through the Copyright Clearance Center, P.O. Box 765, Schenectady, NY 12301. Address requests for reprint permission to the Permissions Office, APA, 1200 Seventeenth Street, N.W., Washington, D.C. 20036.

Subscriptions: Subscriptions are available on a calendar year basis only (January through December). Nonmember rates for 1979: $60 domestic, $64 foreign, $6 single issue. APA member rate: $20. Write to Subscription Section, APA.

Change of Address: Send change of address notice and a recent mailing label to the attention of the Subscription Section, APA, 30 days prior to the actual change of address. APA will not replace undelivered copies resulting from address changes; journals will be forwarded only if subscribers notify the local post office in writing that they will guarantee second-class forwarding postage.

Reprints: Authors may order reprints of their articles from the printer when they receive proofs.

Back Issues and Back Volumes: For information regarding back issues or back volumes write to Order Department, APA.

Microform Editions: For information regarding microform editions write to any of the following: Johnson Associates, Inc., P.O. Box 1017, Greenwich, Connecticut 06830; University Microfilms, Ann Arbor, Michigan 48106; or Princeton Microfilms, Princeton, New Jersey 08540.

Published monthly in one volume per year by the American Psychological Association, Inc., 1200 Seventeenth Street, N.W., Washington, D.C. 20036. Printed in the U.S.A. Second-class postage paid at Arlington, Va., and at additional mailing offices.

Feeling More Than We Can Know: Exposure Effects Without Learning

William Raft Wilson
School of Nursing
University of Michigan

Given the joint occurrence of positive attitudinal and learning effects that typically result from repeated stimulus exposure, most researchers have concluded that what an individual knows and what he or she feels about the familiar stimulus are not independent. In fact, it is generally assumed that some form of learning, such as recognition, both precedes and mediates the affective response. This study questioned that assumption by seeking to obtain positive exposure effects in the absence of stimulus recognition. In order to unconfound affect and learning effects, two experiments with female subjects employed a dichotic-listening procedure for stimulus exposure, in which the critical stimuli were exposed on the unattended channel. Reliable attitudinal enhancement toward objectively familiar stimuli was obtained in both experiments, even though recognition levels were low (Experiment 1) or at chance levels (Experiment 2). Subjective stimulus familiarity was not found to be a significant predictor of affect in either experiment. Positive feelings toward a previously encountered object are not dependent on consciously knowing or perceiving that the object is familiar. Implications for the role of awareness in processes of attitude formation under conditions of mere exposure are discussed.

Research on the cognitive and affective changes that an individual experiences as a function of repeated stimulus exposure has consistently obtained two results. At a cognitive level, the individual's ability to recognize the stimulus increases (e.g., Martin, 1968). At an affective level, the individual's attitude toward the stimulus becomes increasingly positive (e.g., Zajonc, 1968). Given the joint occurrence of these two effects, most researchers have concluded that changes in what an individual knows and in what he or she feels about the familiar stimulus are highly related. In fact, it is generally assumed that some form of learning that improves the individual's ability to identify, classify, or

This research was supported by National Science Foundation Grant GS-35495 to R. B. Zajonc.

The author wishes to thank Robert B. Zajonc for his comments on earlier versions of this manuscript, and Lily Huang for her advice on the data analyses.

recognize the stimulus both precedes and mediates the affective response (Berlyne, 1970; Harrison, 1968; Stang, 1975).

Although the above assumption has been incorporated in all major explanations of the attitudinal effects of stimulus exposure, little research has been designed to test it experimentally. Furthermore, clear support for stimulus recognition or feelings of familiarity as a necessary condition for obtaining exposure effects has not emerged in past research. For example, Matlin (1971) reported that objectively (de facto) familiar stimuli, which were correctly recognized and subjectively familiar, were rated more positively than objectively familiar stimuli that were incorrectly identified and not subjectively familiar. Surprisingly, however, feelings of subjective familiarity did not lead to more positive ratings of stimuli if they were indeed novel. Confidence in these findings should be limited, since comparisons were based on two very infrequent recognition errors. It is possible that these judgment errors may have resulted from certain biases elicited by particular features of the stimuli that also influence affect.

In a direct attempt to connect learning to exposure effects, Stang (1975) performed a number of experiments in which he varied exposure duration and measured subjects' affective ratings of, and ability to recognize or recall, stimuli. Learning and affect curves were found to vary, almost identically, as a function of exposure duration. Stang concluded that repeated stimulus exposure leads to learning that is intrinsically rewarding, and that this reward value is associatively linked to the stimulus. Thus, when asked to rate the familiar stimulus, an individual will reflect this accumulation of reward value by giving a positive rating.

The conclusions drawn from Stang's data are questionable. First, subjects were told that they were participating in a learning study. This may have inflated the relation between stimulus recognition and affect rating, since "good" performance was dependent on accuracy of learning. Other related research suggests that subjects respond differently to stimuli during exposure, once they are informed that recognition will later be measured (e.g., Berlyne, Craw, Salapatek, & Lewis, 1963). Secondly, the joint occurrence of stimulus recognition and positive affect ratings does not in itself demonstrate that learning is a necessary condition for obtaining exposure effects. That learning is not a necessary condition was suggested by recent research that reported a significant partial correlation between exposure and affect, independent of the effects of subjective familiarity (Moreland & Zajonc, 1977).

The fact that, under typical conditions of exposure, subjective familiarity judgments and affective ratings are highly correlated can not be disputed. The critical question that remains to be investigated, however, is whether these effects are partially independent products of repeated stimulus presentations, or whether the enhanced affective response is dependent on increments in subjective familiarity. What is needed is an alternative method for stimulus exposure that can unconfound attitudinal and learning effects. One obvious approach is to establish exposure conditions in which the form of perceptual learning that commonly enhances stimulus recognition is severely attenuated or reduced to chance levels, even after repeated stimulus presentations.

Although repeated presentation of a stimulus to an individual usually does increase the probability that it will be recognized or recalled, studies of selective attention suggests that this is not an inevitable result when the information is not attended to during presentation. For example, the dichotic-listening procedure involves simultaneous transmission of different messages to each of the subject's ears. The subject is required to attend to the information being transmitted to one ear and to ignore the information coming to the other ear. Under these conditions, information in the unattended channel rarely enters consciousness, and its later recognition or recall rarely exceeds chance levels, even when processing up to a semantic level is evident (Corteen & Wood, 1972; Moray, 1959). Thus, the dichotic-listening procedure appears to be an excellent method for establishing conditions of *mere* exposure, that is, for making the stimulus accessible to the individual's percep-

tion (Zajonc, 1968) without increasing the probability of stimulus recognition.

The purpose of the present study was to examine the contribution of objective and subjective familiarity to exposure effects obtained in the absence of stimulus recognition. It was assumed that objectively familiar stimuli would be rated more positively than objectively unfamiliar stimuli, independent of how familiar these stimuli may have appeared to the individual. At the extreme, I sought to obtain the exposure effect in the absence of stimulus recognition.

Experiment 1

A modified dichotic-listening procedure for stimulus exposure was employed. Subjects were required to attend to a distractor message in one ear while the critical stimuli were being transmitted to the unattended ear. The purpose of this experiment was to determine if attitudinal enhancement effects of mere exposure could be obtained when the critical stimuli were presented on the unattended channel.

Method

Subjects

The subjects were 24 undergraduate women enrolled in introductory psychology courses at the University of Michigan. They were randomly drawn from the Department of Psychology voluntary subject pool. Female students were selected for reasons of convenience.

Materials and Apparatus

The critical stimuli were six tone sequences. Each sequence was approximately 10 sec long and appeared, to the listener, to be a simple melody. Each tone sequence consisted of 40 tone units, each unit having a given frequency selected at random from among 10 frequencies varying from 282 Hz to 631 Hz, having a given duration selected at random from among five durations varying from 100 msec to 600 msec, and having one of three loudness levels. The six sequences were of intermediate complexity level, and were chosen from among 18 created by Vitz (1964; 1966). Under ordinary listening conditions, these sequences were found to be clearly discriminable when judged for pleasantness, amount of variation, and complexity (Crozier, 1974; Vitz, 1964; 1966).

Six tapes were prepared for exposure purposes, each of which contained three of the six critical stimuli repeated five times each, for a total of 15 exposure trials per tape with 5-sec intertrial intervals. The order in which the tone sequences were played on any given tape was randomly determined. For purposes of postexposure ratings, a test tape, comprised of all six critical stimuli, randomly ordered, was prepared. Use of each tone sequence for exposure and/or testing was balanced so that half of the subjects were exposed to it prior to testing, while the other half encountered the stimulus only during testing.

The distractor message, to which subjects were asked to attend during the exposure phase, was a taped passage of a story segment taken from Daphne DuMaurier's *The Birds*. This passage was read in a monotone female voice at about 150 words per min. A typewritten version of this passage was prepared which contained a number of "errors." For example, the subject would hear "Autumn was best for this, better than spring," whereas the written passage would read, "*Author* was *been* for this, better *them* spring." There were either 3 or 4 randomly determined errors per line. Whether any particular line had 3 or 4 errors was also randomly determined.

As in previous research (e.g., Zajonc, Markus, & Wilson, 1974), a 7-point bipolar scale was employed to measure affect. The extreme points on this scale were labeled "like" and "dislike." The recognition responses were recorded on a separate sheet. On the left side of the page, the subject checked whether the test stimulus was "OLD" or "NEW." To the right of this judgment were spaces where the subject indicated whether she was sure, half-sure, or guessing when making the recognition judgment.

Both the critical stimuli and the distractor message were recorded and played back on a stereo tape recorder. All stimuli were heard by the subjects over stereo headphones. The subjects were seated at library-type desks, which prevented them from seeing the experimenter, or any of the equipment, during the experiment. Finally, volume levels for both the distractor message and the critical stimuli were measured by a sound meter.

Procedure

Exposure phase. The subjects were asked to sit down immediately upon arriving and were read the following instructions:

> Before you is a copy of a literary passage. I would like you to do two things: (1) listen to someone recite that passage while you simultaneously read the text and (2) put a slash through all words in the written text which do not correspond to the words you hear. This is like a proofreading task where all noncorresponding words are considered errors. In order to do your best at this task, you will have to listen very closely to what the speaker is saying. There will be many errors in the written text and your job

is to put a slash through as many as you can discover. If you have no questions, we will now have a short practice session.

The subject was then given eight lines of practice. Then the entire passage was played to the subject's right ear without any interruptions. Approximately 30 sec after the passage had started, the critical stimuli were played to the subject's left ear.[1] The distractor passage continued for 30 sec after the exposure phase was completed. The subjects were not forewarned about the occurrence of the critical stimuli, but they were instructed to ignore any extraneous sounds, regardless of the source, and to focus their complete attention on the literary passage. The distractor passage was played at a volume of approximately 60 dB (B)[2] and the critical stimuli at approximately 55 dB.

Testing phase. After the exposure phase, the subjects were given the following instructions for the recognition test:

I am now going to play six tone sequences that sound much like simple melodies. Three of the tone sequences you will hear were played to you during the proofreading task. Three of the tone sequences you will hear will be ones played to you for the first time. What I would like you to do is to indicate, for each tone sequence, whether or not you think it was played during the proofreading task.

The subjects were then shown how to use the recognition and confidence scales. The same set of instructions was provided for the affective ratings, with the exception that the subjects were asked to indicate how they felt toward each tone sequence. Up to 30 sec per stimulus was allowed for making a recognition or affective judgment.

To control for possible order effects, judgment of affect and recognition were counterbalanced. Half of the subjects made recognition judgments first and then gave affect ratings, while the opposite was true for the other subjects.

Results

Recognition

On the average, the subjects were able to identify correctly 3.54 of the test stimuli as OLD or NEW.[3] Analysis of this average, in comparison with the average recognition that would be expected by chance (3.00), reveals that the subjects did better than chance, $t(23) = 2.41$, $p < .05$. Thus, the method of exposure employed in this experiment appears to be relatively effective for attenuating recognition; however, it is not sufficient for eliminating recognition entirely.[4]

Affect

Responses on the affect scale were converted to numbers ranging from 0 to 6, with 6 indicating the most positive response. Each subject's ratings of stimuli in each of the four cells (e.g., "OLD"/NEW) were then averaged. If a subject did not provide ratings for stimuli in a particular cell, for example, if no OLD stimuli were identified as "OLD" by that subject, that cell was given an estimated value in the form of the subject's average rating of stimuli in all other cells combined. This procedure allowed for a straightforward comparison of the effects of objective and subjective familiarity on affective rating of stimuli. The means of both the adjusted and unadjusted ratings appear in Table 1.

A $2 \times 2 \times 2$ analysis of variance for repeated measures, with one between-subjects factor (order of judgment–affect or recognition first) and two within-subjects factors (objective familiarity—OLD vs. NEW; and subjective familiarity—"OLD" vs. "NEW"), was performed on the adjusted affect ratings. The results show no significant main effect for Order of Judgment, $F(1, 22) < 1$. They do reveal, however, that the subjects rated OLD stimuli more positively than NEW stimuli, regardless of whether they were judged "OLD" or "NEW," $F(1, 22) = 11.66$, $p < .005$ (Table

---

[1] The left ear was selected because research suggests that, in general, musical patterns are better processed and better recognized later when played to the right hemisphere (cf. Bever & Chiarello, 1974; Kimura, 1973).

[2] re 20 $\mu N/m^2$.

[3] Stimuli that appeared in the training series are designated as OLD whereas those that appeared in testing only are designated as NEW. The subjects' responses are designated as "OLD" and "NEW."

[4] In earlier pilot research to establish the validity of the recognition measure and to confirm the discriminability of the tone sequences, 12 subjects were asked to attend to the critical stimuli (rather than the distractor passage) during the exposure phase and then to do the recognition test. As might be expected under these conditions, the subjects made no errors (100% accuracy) in classifying previously exposed tone sequences as "OLD" and tone sequences exposed for the first time during testing as "NEW." Thus, there appears to be quite a substantial reduction in recognition accuracy when the tone sequences are presented on the unattended channel.

2). There is also a marginally significant tendency for the subjects to rate stimuli that they judged as "OLD" more positively than stimuli judged as "NEW," regardless of whether or not the stimulus was objectively OLD or NEW, $F(1, 22) = 3.41$, $p < .10$.

Even though the Objective Familiarity × Subjective Familiarity interaction is not significant, it is of interest to examine, separately, the ratings of objective familiar stimuli called "OLD" and "NEW." For stimuli judged "OLD," truly OLD stimuli were liked better than NEW stimuli, although this effect is not significant, $F(1, 22) = 2.23$. This effect, however, is reliable for stimuli judged "NEW": Truly OLD stimuli were liked better than truly NEW stimuli, $F(1, 22) = 7.40$, $p < .05$. Thus the exposure effect was obtained even in the absence of the subject's awareness of his own differential experience with the stimuli.

The relationship between affect ratings and subjective familiarity was further examined by combining recognition and confidence judgments into a single measure of subjective familiarity. Each stimulus was classified as to its degree of oldness, ranging from "OLD-SURE" (6) to "NEW-SURE" (1). Then each subject's average oldness rating and average affect rating were correlated for OLD and NEW stimuli, separately. The correlations obtained for NEW and OLD stimuli were −.29 and .14 ($df = 22$), respectively. In the case of objectively NEW stimuli, a negative correlation indicates that the more certain the subject was that the stimulus was "NEW," the better she liked it. Conversely, in the case of OLD stimuli, a positive correlation indicates that the more certain the subject was that the stimulus was "OLD," the better she liked it. In short, although neither of the above correlations is significant, they are in the direction of a positive relationship between liking and degree of subjective certainty about the true familiarity of the stimulus. Because the correlation was positive for OLD stimuli and negative for NEW stimuli, these results do not indicate that affective ratings depend, to any significant degree, on oldness ratings per se. If the latter were true, we would expect a positive correlation between oldness and affect ratings, for *both* OLD and NEW stimuli.

Intercorrelations among all the measures are provided in Table 2.

Table 1
Average Stimulus Affect Ratings as a Function of Objective Familiarity (OLD–NEW) and Subjective Familiarity ("OLD"–"NEW")

Objective familiarity	Subjective familiarity "OLD"	Subjective familiarity "NEW"	*M*
OLD	4.22 (4.16)	4.00 (4.11)	4.12 (4.12)
NEW	3.77 (3.33)	3.04 (3.19)	3.30 (3.23)
M	4.02 (3.83)	3.52 (3.60)	

Note. Figures without parentheses include estimated values for some subjects. The number of subjects for which values are estimated is 2, 4, 6, and 1 for the "OLD"/OLD, "NEW"/OLD, "OLD"/NEW, and "NEW"/NEW cells, respectively. Responses on the affect scale range from 0 to 6, with 6 indicating the most positive evaluation.

Table 2
Intercorrelations Among the Measures

Measure	1	2	3	4
1. Affect	1.00			
2. Objective familiarity	.26**	1.00		
3. Subjective familiarity	.07	.18*	1.00	
4. Oldness	.09	.15	.88***	1.00

Note. Objective familiarity was controlled by the experimenter and refers to the true degree of contact that the subject had with the stimulus. The other variables were under the subject's control. The oldness response is comprised of both the subject's familiarity ("OLD" or "NEW") judgment and the confidence ("SURE," "HALF-SURE," or "GUESS") rating of that judgment.
* $p < .05$.
** $p < .01$.
*** $p < .001$.

Experiment 2

The procedure employed in the first experiment proved to be relatively successful in attenuating recognition accuracy, but it did not reduce it to a chance level. Nevertheless, under those conditions, objective familiarity was found to influence affective ratings, inde-

pendently of other processes. To some extent, subjective familiarity and subjective certainty were found to be related to affective judgments, as well. Whether these same effects would be observed under conditions in which subjects could not recognize the critical stimuli at better than chance levels remained to be demonstrated. Therefore, in this second experiment, a modified procedure was employed in order to eliminate all reliable recognition; during stimulus exposure, the subjects were required to verbally shadow the distractor message and simultaneously do the proofreading task.

To gain a better understanding of the cognitive and affective changes that result when the critical stimuli are exposed in this unobtrusive fashion, two additional measures, found in past research to be sensitive to levels of stimulus familiarity, were employed. The first measure was latency of recognition judgments. In general, familiar stimuli are recognized not only better but also faster than less familiar stimuli are (cf. Matlin, 1971). It is possible that subjects respond faster to objectively familiar stimuli, even when they do not recognize them as familiar. This finding would suggest that, even in the absence of stimulus recognition, there may be some form of differential cognitive processing of de facto familiar and unfamiliar stimuli.

The second new measure was an indicator of the subject's level of arousal when evaluating each stimulus, namely, galvanic skin response (GSR). Both Berlyne et al. (1963) and Zajonc (1968) have reported that novel stimuli evoke a greater drop in skin resistance than do familiar stimuli. Even in the absence of stimulus recognition, such physiological differences in response to de facto familiar and unfamiliar stimuli may occur, given that changes in skin resistance are a function of information (about the stimulus) that is not used in making the recognition judgment (see Eriksen, 1960).

Method

Subjects

The subjects were 24 undergraduate women enrolled in introductory psychology courses at the University of Michigan. They were randomly drawn from the Department of Psychology voluntary subject pool.

Materials and Apparatus

The critical stimuli and the distractor message were the same as those employed in Experiment 1. All the equipment used in the first experiment was employed in this experiment. In addition, a response panel was constructed to register the subject's recognition and confidence judgments. The subject made her recognition and confidence judgments by pressing the appropriate buttons on the response panel "OLD" or "NEW" for recognition, and "SURE," "HALF-SURE," or "GUESS" for confidence judgments. The subject's response activated a light that indicated to the experimenter which response had been made. The latency of the subject's response was recorded by a clock, outside of the subject's vision.

Changes in skin resistance (GSR) were measured on an event recorder, connected to a control unit and to Lykken zinc-zinc sulphate electrodes. The skin resistance was recorded for each subject on a scale calibrated at 500 k-ohms, with a 600 k-ohms limit. This system relies on a 10-μV current (see Kaplan & Hobart, 1964). Change in skin resistance was arbitrarily defined as the distance in ohm units between the lowest and highest point of resistance within a 20-sec period immediately following stimulus onset. Affect ratings were obtained in the same way as in Experiment 1.

Procedure

Exposure phase. When the subject arrived, the experimenter connected the electrodes to the first and third fingers of the subject's nonpreferred hand. The subject was told that the electrodes would cause no inconvenience, other than that due to their presence, and that the purpose of the electrodes would be explained after the experiment. The subject was then seated at the experimental desk and read the following instructions:

> You are about to hear, over these headphones, a literary passage read by a young woman. I would like you to do two things. First, repeat each word that this person says, immediately after you hear it. She will be speaking at a fairly fast rate, so you will have to work hard to keep up with her. If you should fall behind by more than two or three words, start again with the last word that she has just spoken. I will be recording your repetition of the passage on the microphone sitting before you, so be sure to speak loudly and clearly. Secondly, while you are listening to and repeating what the woman is saying, I would like you to read the text before you. When you see a word that does not correspond to what you are hearing and saying, put a slash through it. This is like

proofreading task where all noncorresponding words are considered errors. In order to do your best at this task, you will have to listen very closely to what the speaker is saying. There will be many errors in the written text, and your job is to put a slash through as many as you can discover. If you have no questions, we will now have a short practice session.

The subject was then given eight lines of practice, followed by a restatement of the task requirements. The rest of the exposure phase was the same as in Experiment 1.

Testing phase. The instruction and procedure employed for testing was comparable to that used in Experiment 1. In this experiment, however, the subject was instructed on how to use the apparatus for indicating recognition judgments; also, the fact that half of the stimuli were truly OLD was emphasized again, just prior to testing.

Results

Recognition

The subjects identified stimuli as "OLD" or "NEW," independently of their true exposure history, with an overall average level of accuracy of only 3.17, $t(23) < 1$. Thus, the method of exposure employed in this experiment achieved the desired condition of chance recognition.

Table 3
Average Stimulus Affect Ratings as a Function of Objective Familiarity (OLD–NEW) and Subjective Familiarity ("OLD"–"NEW")

Objective familiarity	Subjective familiarity "OLD"	Subjective familiarity "NEW"	*M*
OLD	3.51 (3.61)	3.85 (3.87)	3.66 (3.72)
NEW	3.03 (3.08)	3.02 (3.06)	3.03 (3.07)
M	3.29 (3.36)	3.40 (3.42)	

Note. Figures without parentheses include estimated values for some subjects. The number of subjects for which values are estimated is 2, 5, 2, and 2 for the "OLD"/OLD, "NEW"/OLD, "OLD"/NEW, and "NEW"/NEW cells, respectively. Responses on the affect scale range from 0 to 6, with 6 indicating the most positive evaluation.

Table 4
Average Recognition Judgment Latencies (in sec) as a Function of Objective Familiarity (OLD–NEW) and Subjective Familiarity ("OLD"–"NEW")

Objective familiarity	Subjective familiarity "OLD"	Subjective familiarity "NEW"	*M*
OLD	12.12 (12.34)	11.76 (11.53)	11.97 (11.99)
NEW	13.35 (13.52)	11.17 (11.61)	12.26 (12.57)
M	12.70 (12.89)	11.44 (11.57)	

Note. Figures without parentheses include estimated values for some subjects. The number of subjects for which values are estimated is 2, 5, 2, and 2 for the "OLD"/OLD, "NEW"/OLD, "OLD"/NEW, and "NEW"/NEW cells, respectively.

Affect

Liking ratings were scored and analyzed as described in the first experiment. Again, no significant effects were obtained for Order of Judgment, $F(1, 22) < 1$. As we can see in Table 3, OLD stimuli were rated more positively than NEW stimuli, regardless of whether they were judged "OLD" or "NEW," $F(1, 22) = 5.71$, $p < .05$, a finding that is consistent with the one obtained in Experiment 1. Now, however, subjective familiarity has no influence on affect ratings, $F(1, 22) < 1$, and once again, no significant effects are observed for the Objective Familiarity × Subjective Familiarity interaction, or for any other interaction.

When the main effect of objective familiarity is decomposed, the pattern of results obtained is similar to that found in the first experiment. OLD stimuli were liked somewhat more than NEW stimuli, even when both were identified as "OLD"; but the effect was not significant, $F(1, 22) = 1.51$. However, the exposure effect was again obtained without the subject having been aware of her differential experience with the tone sequences, in that OLD stimuli were liked significantly more than NEW stimuli, even when both were judged as "NEW," $F(1, 22) = 6.89$, $p < .05$.

As in Experiment 1, a 6-point oldness measure of subjective familiarity was obtained by combining recognition and confidence judgments. The average oldness ratings and the average affect ratings were correlated for OLD and NEW stimuli, separately. The coefficients suggest little relation between affect and subjective familiarity or subjective certainty—for OLD stimuli $r(22) = .09$, and for NEW stimuli $r(22) = -.02$.

GSR and Latency

GSR and recognition latency scores were subjected to the same analysis as affect ratings. Little systematic variation in skin resistance was obtained among the different cells. Analysis revealed no significant effect for order of judgment, objective familiarity, subjective familiarity, or the OLD × "OLD" interaction.

Table 4 presents average latency responses. Neither order of judgment, $F(1, 22) = 1.49$, nor objective familiarity, $F(1, 22) < 1$, emerged as a significant factor. There is a reliable difference between latency of "OLD" and "NEW" judgments, $F(1, 22) = 8.36$, $p < .01$, the average difference being 1.25 sec. There were no significant interactions.

Intercorrelations among all the measures are provided in Table 5.

General Discussion

When the attitudinal and learning effects produced by repeated stimulus exposure are unconfounded, an interesting pattern of results emerges. First, reliable exposure effects are obtained, that is, previously encountered stimuli are rated more positively than novel stimuli. Second, subjective judgments of stimulus familiarity are not reliably related to affective evaluations, even when confidence ratings are considered. Together, these results suggest that an individual's positive feelings toward a previously encountered object are not dependent on his consciously knowing or perceiving that the object is familiar. Such findings have important implications for the role of awareness in processes of attitude formation under conditions of mere exposure.

Explanations of the Exposure Effect

The first major explanation of the attitudinal effects of exposure is the *response competition* hypothesis proposed by Harrison (1968). He suggested that when a stimulus is first encountered, it elicits a number of response tendencies that compete for emission. This induction of response competition leads to a state of tension in the individual, characterized by "negative affect and a motivational impetus to eliminate the tension" (p. 363). With repeated exposure of the stimulus, however, only a limited number of compatible response tendencies achieve ascendancy. The end result of repeated stimulus presentations is a reduction in response competition, which is reflected by an increment of positive affect

Table 5
Intercorrelations Among the Measures

Measure	1	2	3	4	5	6
1. Affect	1.00					
2. Objective familiarity	.18*	1.00				
3. Subjective familiarity	−.02	.07	1.00			
4. Oldness	−.05	.10	.85**	1.00		
5. Latency	.06	−.06	.13	.08	1.00	
6. Galvanic skin response	−.05	−.01	.05	.03	−.10	1.00

Note. Objective familiarity was controlled by the experimenter and refers to the true degree of contact that the subject had with the stimulus. The other variables were under the subject's control. The oldness response is comprised of both the subject's familiarity ("OLD" or "NEW") judgment and the confidence ("SURE," "HALF-SURE," or "GUESS") rating of that judgment.

* $p < .05$.

** $p < .001$.

for the familiar stimulus. Although the point is never made explicitly by Harrison, it is clear that stimulus recognition is a sine qua non for the reduction of response competition, that is, access to, and retrieval of, previously stored associations is contingent on the elicitation of a stable encoding response by the individual over successive exposures (cf. Höffding, 1891). Thus, an individual must correctly identify the stimulus in order to have access to past associations (response tendencies) that have been linked to it (cf. Lawrence, 1963; Martin, 1968).

A second major explanation of exposure effects is a *two-factor* learning theory proposed by Berlyne (1970). He postulated that individuals have a preference for some optimal level of arousal. When extremely novel or complex stimuli are encountered, arousal is increased above the optimal level and the stimuli elicit low or even negative affect in the individual. But with repeated encounters, the arousal potential of the stimuli declines because they are processed with greater ease and are better understood. Thus, familiar stimuli will be favorably evaluated following exposure, because the individual's arousal level is modified back toward the optimum. Berlyne reasoned that "opportunities for further acquaintance with the pattern will provide scope for the perceptual and ideational processing that enables uncertainty and conflict to be resolved as elements are discriminated, classified, recognized, and grouped together as sub-wholes. This can evidently be a source of pleasure, presumably dependent on the arousal-reduction mechanism" (p. 285). Clearly, the role of stimulus recognition is central to this theory as well.

Obviously, the present results raise questions about the validity of the above theories or any other explanations of exposure effects that implicitly include overt stimulus recognition as a prerequisite for obtaining enhanced affect (e.g., Burgess & Sales, 1971; Crandall, 1967). In the current experiments, it is unlikely that the subjects were able to engage in strategies to reduce uncertainties, form associations, and/or systematically explore the critical stimuli in order to promote subsequent recognition ability. Furthermore, the data clearly suggest that subjective familiarity, veridical or otherwise, does not influence affective responses to previously encountered stimuli in a simple fashion, in such a way that the former always precedes and mediates the latter. Thus, one must question any theory that assumes that individuals must be aware of their past experiences with the stimulus as a sine qua non for obtaining the frequency–affect relationship.

In a related vein, some researchers (e.g., Stang, 1974) have suggested that exposure effects may result from demand characteristics, because the subject is "aware" of the familiarity–affect hypothesis and responds accordingly. Even granting that such awareness was present in these experiments, it would be of little use to the subjects, since they could not reliably determine which stimuli they had heard previously. Thus it is difficult to interpret the present results as artifactual. One might argue, however, that if subjects were aware of the familiarity–affect hypothesis and were conforming to demand characteristics, they would consistently assign high affect ratings to stimuli that they judged to be familiar and low ratings to stimuli judged unfamiliar. The data reveal no such effects.

The Role of Awareness

Although the results from this study do not provide a sufficient basis for generating an alternative model to account for exposure effects, they do suggest that if learning processes underlie these effects, those processes may not require conscious awareness or effort by the subject.[5] In other words, one might argue that the subjects did engage in some form of learning during exposure (i.e., developed expectancies, reduced uncertainty, alleviated response competition, and the like) but not at the level of conscious awareness. Such lack of awareness during exposure may have prevented the subjects from later re-

[5] It is interesting to note that frequency information appears to be encoded with little effort or conscious intent by individuals (Hasher & Chromiak, 1977; Howell, 1973a, 1973b).

liably retrieving, from memory, information about the occurrence of the stimulus (cf. Melton & Martin, 1972), but the affective response was not impaired because learning without awareness had occurred. The plausibility of such an explanation is suggested by recently developed models of human information processing that question the necessity (Erdelyi, 1974) and even the efficacy (Nisbett & Wilson, 1977) of conscious awareness of processes underlying affective reactions.

Related demonstrations of such effects have been reported in studies of perception and learning without awareness. For example, pictures presented too briefly (1 msec) to obtain correct verbal identification or recognition responses nevertheless produced reliable differences in evoked potentials (average evoked response) and interpretable free associations (Shevrin & Fritzler, 1968; Shevrin, Smith, & Fritzler, 1971). Employing a dichotic-listening procedure, Konecni and Slamecka (1972) found that verbal conditioning effects could be obtained even when subjects were not aware of the verbal reinforcer presented on the unattended channel.

The merit of a learning-without-awareness explanation of exposure effects needs, however, to be demonstrated. No evidence in the present results can be invoked to support or deny such a process. Support for a theory that postulates that the exposure effect is mediated by a completely covert learning process must demonstrate that this process occurs prior to affect changes, and must employ measures that are independent of such changes.

Conclusions

If exposure effects need not involve the individual's awareness of the familiarization process, then the influences of proximity and familiarity on attitude formation may be even more pervasive than originally suspected. It has been established that objects and individuals we *knowingly* encounter or interact with (even incidentally) are likely to come to be regarded positively (Festinger, Schachter, & Back, 1950; Saegert, Swap, & Zajonc, 1973; Segal, 1974; Zajonc, 1968). The present results raise the possibility that the objects and individuals we encounter in our environment are likely to engender a positive orientation, regardless of our knowledge of past encounters with them. Thus, in some cases, what we feel about objects or individuals may precede our "awareness" of previous contact! One might speculate that, in the extreme case, unconsciously formed positive attitudes toward "novel" objects or "strangers" in our environment stimulate both an awareness of their existence and conscious attempts to obtain knowledge about them. Whereas prior research has focused largely on how learning mediates affect, we should consider more seriously the Moreland and Zajonc (1977) proposition that changes in affect following exposure may influence learning.[6]

Obviously, the validity of such speculations must be determined by additional research. The results from the present study suggest that future work may require a departure from traditional methods of studying exposure effects and, to some extent, a change in assumptions about the conditions under which these effects can occur. Such research must determine whether familiarity mediates affect directly, without the intervention of other processes, and, if so, whether changes in affect influence learning processes. Finally, we need to examine more explicitly the role of awareness in exposure effects, in order to better understand how familiarity breeds liking.

---

[6] In a recent article, Birnbaum and Mellers (1979) are critical of the partial correlation technique employed by Moreland and Zajonc (1977) to determine that affect and recognition are two independent outcomes of stimulus exposure (i.e., that these responses are mediated by two different mechanisms). They argue that a single mediator, labeled *subjective recognition*, could account for both the affect and the recognition responses obtained by Moreland and Zajonc under the very likely conditions that measures of these two responses are not perfectly correlated. The present results appear to make some aspects of their thesis questionable. In contrast to Moreland and Zajonc's technique, the recognition factor in the present study was partialed out of the effects experimentally rather than statistically, but affect was still found to be reliably related to objective frequency.

Many Hands Make Light the Work: The Causes and Consequences of Social Loafing

Bibb Latané, Kipling Williams, and Stephen Harkins
Ohio State University

Two experiments found that when asked to perform the physically exerting tasks of clapping and shouting, people exhibit a sizable decrease in individual effort when performing in groups as compared to when they perform alone. This decrease, which we call social loafing, is in addition to losses due to faulty coordination of group efforts. Social loafing is discussed in terms of its experimental generality and theoretical importance. The widespread occurrence, the negative consequences for society, and some conditions that can minimize social loafing are also explored.

There is an old saying that "many hands make light the work." This saying is interesting for two reasons. First, it captures one of the promises of social life—that with social organization people can fulfill their individual goals more easily through collective action. When many hands are available, people often do not have to work as hard as when only a few are present. The saying is interesting in a second, less hopeful way—it seems that when many hands are available, people actually work less hard than they ought to.

Over 50 years ago a German psychologist named Ringelmann did a study that he never managed to get published. In rare proof that unpublished work does not necessarily perish, the results of that study, reported only in summary form in German by Moede (1927), have been cited by Dashiell (1935), Davis (1969), Köhler (1927), and Zajonc (1966) and extensively analyzed by Steiner (1966, 1972) and Ingham, Levinger, Graves, and Peckham (1974). Apparently Ringelmann simply asked German workers to pull as hard as they could on a rope, alone or with one, two, or seven other people, and then he used a strain gauge to measure how hard they pulled in kilograms of pressure.

Rope pulling is, in Steiner's (1972) useful classification of tasks, maximizing, unitary, and additive. In a maximizing task, success depends on how much or how rapidly something is accomplished and presumably on how much effort is expended, as opposed to an optimizing task, in which precision, accuracy, or correctness are paramount. A unitary task cannot be divided into separate subtasks—all members work together doing the same thing and no division of labor is possible. In an additive task, group success depends on the *sum* of the individual efforts, rather than on the performance of any subset of members. From these characteristics, we should expect three people pulling together on a rope with perfect efficiency to be able to exert three times as much force as one person can, and eight people to exert eight times as much force.

Ringelmann's results, however, were strikingly different. When pulling one at a time, individuals averaged a very respectable 63 kg of pressure. Groups of three people were able to exert a force of 160 kg, only two and a

half times the average individual performance, and groups of eight pulled at 248 kg, less than four times the solo rate. Thus the collective group performance, while increasing somewhat with group size, was substantially less than the sum of the individual efforts, with dyads pulling at 93% of the sum of their individual efforts, trios at 85%, and groups of eight at only 49%. In a way somewhat different from how the old saw would have it, many hands apparently made light the work.

The Ringelmann effect is interesting because it seems to violate both common stereotype and social psychological theory. Common stereotype tells us that the sense of team participation leads to increased effort, that group morale and cohesiveness spur individual enthusiasm, that by pulling together groups can achieve any goal, that in unity there is strength. Social psychological theory holds that, at least for simple, well-learned tasks involving dominant responses, the presence of other people, whether as co-workers or spectators, should facilitate performance. It is thus important to find out whether Ringelmann's effect is replicable and whether it can be obtained with other tasks.

The Ringelmann effect is also interesting because it provides a different arena for testing a new theory of social impact (Latané, 1973). Social impact theory holds that when a person stands as a target of social forces coming from other persons, the amount of social pressure on the target person should increase as a multiplicative function of the strength, immediacy, and number of these other persons. However, if a person is a member of a group that is the target of social forces from outside the group, the impact of these forces on any given member should diminish in inverse proportion to the strength, immediacy, and number of group members. Impact is divided up among the group members, in much the same way that responsibility for helping seems to be divided among witnesses to an emergency (Latané & Darley, 1970). Latané further suggests that just as psychophysical reactions to external stimuli can be described in terms of a power law (Stevens, 1957), so also should reactions to social stimuli, but with an exponent having an absolute value less than 1, so that the nth person should have less effect than the $(n-1)$th. Ringelmann's asking his workers to pull on a rope can be considered social pressure. The more people who are the target of this pressure, the less pressure should be felt by any one person. Since people are likely to work hard in proportion to the pressure they feel to do so, we should expect increased group size to result in reduced efforts on the part of individual group members. These reduced efforts can be called "social loafing"—a decrease in individual effort due to the social presence of other persons. With respect to the Ringelmann phenomenon, social impact theory suggests that at least some of the effect should be due to reduced efforts on the part of group participants, and that this reduced effort should follow the form of an inverse power function having an exponent with an absolute value less than one.

The Ringelmann effect is interesting for a third reason: If it represents a general phenomenon and is not restricted to pulling on a rope, it poses the important practical question of when and why collective efforts are less efficient than individual ones. Since many components of our standard of life are produced through one form or another of collective action, research identifying the causes and conditions of inefficient group output and suggesting strategies to overcome these inefficiencies is clearly desirable.

For these three and other reasons, we decided to initiate a program of research into the collective performance of individuals in groups.

Experiment 1

Clap Your Hands and Shout Out Loud

One of the disadvantages of Ringelmann's rope pulling task is that the equipment and procedures are relatively cumbersome and inefficient. Therefore, we decided to keep our ears open for other tasks that would allow us to replicate the Ringelmann finding conceptually and would provide the basis for extended empirical and theoretical analysis. We chose cheering and clapping, two activities

that people commonly do together in social settings and that are maximizing, unitary, and additive. As with rope pulling, output can be measured in simple physical units that make up a ratio scale.

Method

On eight separate occasions, groups of six undergraduate males were recruited from introductory psychology classes at Ohio State University; they were seated in a semicircle, 1 m apart, in a large soundproofed laboratory and told, "We are interested in judgments of how much noise people make in social settings, namely cheering and applause, and how loud they seem to those who hear them. Thus, we want each of you to do two things: (1) Make noises, and (2) judge noises." They were told that on each trial "the experimenter will tell you the trial number, who is to perform and whether you are to cheer (Rah!) or clap. When you are to begin, the experimenter will count backwards from three and raise his hand. Continue until he lowers it. We would like you to clap or cheer for 5 seconds as loud as you can." On each trial, both the performers and the observers were also asked to make magnitude estimates of how much noise had been produced (Stevens, 1966). Since these data are not relevant to our concerns, we will not mention them further.

After some practice at both producing and judging noise, there were 36 trials of yelling and 36 trials of clapping. Within each modality, each person performed twice alone, four times in pairs, four times in groups of four, and six times in groups of six. These frequencies were chosen as a compromise between equating the number of occasions on which we measured people making noise alone or in groups (which would have required more noisemaking in fours and sixes) and equating the number of individual performances contributing to our measurements in the various group sizes (which would have required more noisemaking by individuals and pairs). We also arranged the sequence of performances to space and counterbalance the order of conditions over each block of 36 trials, while making sure that no one had to perform more than twice in a row.

Performances were measured with a General Radio sound-level meter, Model 1565A, using the C scale and the slow time constant, which was placed exactly 4 m away from each performer. The C scale was used so that sounds varying only in frequency or pitch would be recorded as equally loud. Sound-level meters are read in decibel (dB) units, which are intended to approximate the human reaction to sound. For our purposes, however, the appropriate measure is the effort used in generating noise, not how loud it sounds. Therefore, our results are presented in terms of dynes/cm^2, the physical unit of work involved in producing sound pressure.

Because people shouted and clapped in full view and earshot of each other, each person's performance could affect and be affected by the others. For this reason, the group, rather than the individual, was the unit of analysis, and each score was based on the average output per person. Results were analyzed in a $4 \times 2 \times 2$ analysis of variance, with Group Size (1, 2, 4, 6), Response Mode (clapping vs. shouting), and Replications (1, 2) as factors.

Results

Participants seemed to adapt to the task with good humor if not great enthusiasm. Nobody refused to clap or shout, even though a number seemed somewhat embarrassed or shy about making these noises in public. Despite this, they did manage to produce a good deal of noise. Individuals averaged 84 dB (C) clapping and 87 dB cheering, while groups of six clapped at 91 dB and shouted at 95 dB (an increment of 6 dB represents a doubling of sound pressure).

As might be expected, the more people clapping or cheering together, the more intense the noise and the more the sound pressure produced. However, it did not grow in proportion to the number of people: The average sound pressure generated *per person* decreased with increasing group size, $F(3, 21) = 41.5$, $p < .001$. People averaged about 3.7 dynes/cm^2 alone, 2.6 in pairs, 1.8 in foursomes, and about 1.5 in groups of six (Figure 1). Put another way, two-person groups performed at only 71% of the sum of their individual capacity, four-person groups at 51%, and six-person groups at 40%. As in pulling ropes, it appears that when it comes to clapping and shouting out loud, many hands do, in fact, make light the work.

People also produced about 60% more sound power when they shouted than when they clapped, $F(1, 7) = 8.79$, $p < .01$, presumably reflecting physical capacity rather than any psychological process. There was no effect due to blocks of trials, indicating that the subjects needed little or no practice and that their performance was not deleteriously affected by fatigue. In addition, there were no interactions among the variables.

Discussion

The results provide a strong replication of Ringelmann's original findings, using a com-

pletely different task and in a different historical epoch and culture. At least when people are making noise as part of a task imposed by someone else, voices raised together do not seem to be raised as much as voices raised alone, and the sound of 12 hands clapping is not even three times as intense as the sound of 2.

Zajonc's (1965) elegant theory of social facilitation suggests that people are aroused by the mere presence of others and are thus likely to work harder (though not necessarily to achieve more) when together. Although social facilitation theory might seem to predict enhanced group performance on a simple task like clapping or shouting, in the present case it would not predict any effect due to group size, since the number of people present was always eight, six participants and two experimenters. Evaluation apprehension theory (Cottrell, 1972) would also not predict any effect as long as it is assumed that coactors and audience members are equally effective in arousing performance anxiety. Therefore, these theories are not inconsistent with our position that an unrelated social process is involved. The results of Experiment 1 also can be taken as support for Latané's (1973) theory of social impact: The impact that the experimenters have on an individual seems to decrease as the number of coperformers increases, leading to an apparent drop in individual performance, a phenomenon we call social loafing.

However, there is an alternative explanation to these results. It may be, not that people exert less effort in groups, but that the group product suffers as a result of group inefficiency. In his invaluable theoretical analysis of group productivity, Steiner (1972) suggests that the discrepancy between a group's potential productivity (in this case n times the average individual output) and its actual productivity may be attributed to faulty social process. In the case of Ringelmann's rope pull, Steiner identifies one source of process loss as inadequate social coordination. As group size increases, the number of "coordination links," and thus the possibility of faulty coordination (pulling in different directions at different times), also increases.

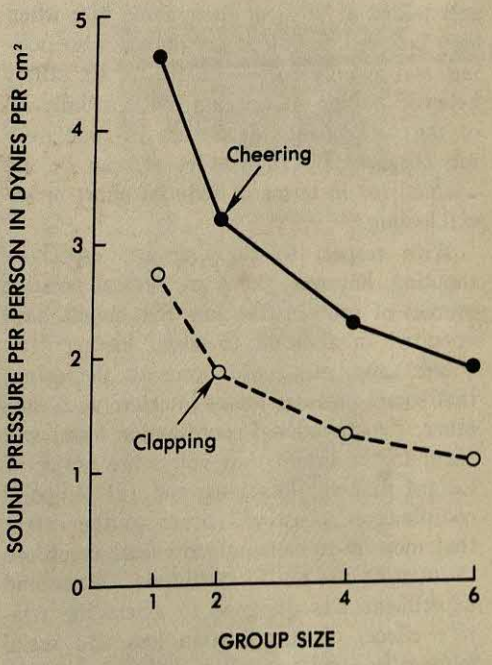

Figure 1. Intensity of noise as a function of group size and response mode, Experiment 1.

Steiner shows that for Ringelmann's original data the decrement in obtained productivity is exactly proportional to the number of coordination links.

Ingham et al. (1974) designed an ingenious experiment to determine whether the process losses found in rope pulling were mainly due to problems of coordinating individual efforts and the physics of the task, or whether they resulted from reductions in personal exertion (what we have called social loafing). First, they conducted a careful replication of Ringelmann's original rope-pulling study and found similar results—dyads pulled at 91% of the sum of their individual capacities, trios at 82%, and groups of six at only 78%.

In a second experiment, Ingham et al. cleverly arranged things so that only the individual's perception of group size was varied. Individuals were blindfolded and led to believe that others were pulling with them, but in fact, they always pulled alone. Under these conditions, of course, there is no possibility of loss due to faulty synchronization. Still there was a substantial drop in output with increases in perceived group size: Individ-

uals pulled at 90% of their alone rate when they believed one other person was also pulling, and at only 85% with two to six others believed pulling. It appears that virtually all of the performance decrement in rope pulling observed by Ingham et al. can be accounted for in terms of reduced effort or social loafing.

With respect to clapping and especially shouting, however, there are several possible sources of coordination loss that might have operated in addition to social loafing: (a) Sound cancellation will occur to the extent that sound pressure waves interfere with each other, (b) directional coordination losses will occur to the extent that voices are projected toward different locations, and (c) temporal coordination losses will occur to the extent that moment-to-moment individual variations in intensity are not in synchrony. Our second experiment was designed to assess the relative effects of coordination loss and social loafing in explaining the failure of group cheering to be as intense as the sum of individual noise outputs.

Experiment 2

Coordination Loss or Reduced Effort?

For Experiment 2 we arranged things so that people could not hear each other shout; participants were asked to wear headphones, and during each trial a constant 90-dB recording of six people shouting was played over the earphones, ostensibly to reduce auditory feedback and to signal each trial. As a consequence, individuals could be led to believe they were shouting in groups while actually shouting alone. Ingham et al. (1974) accomplished this through the use of "pseudosubjects," confederates who pretended to be pulling with the participants but who in fact did not pull any weight at all. That is an expensive procedure—each of the 36 participants tested by Ingham et al. required the services of 5 pseudosubjects as well as the experimenter. We were able to devise a procedure whereby, on any given trial, one person could be led to believe that he was performing in a group, while the rest thought he was performing alone. Thus, we were able to test six real participants at one time.

Additionally, although we find the interpretation offered by Ingham et al. plausible and convincing, the results of their second experiment are susceptible to an alternative explanation. When participants were not pulling the rope, they stood and watched the pseudosubjects pull. This would lead people accurately to believe that while they were pulling the rope, idle participants would be watching (Levinger, Note 1). Thus, as the number of performers decreased, the size of the audience increased. According to Cottrell's evaluation apprehension hypothesis (1972), the presence of an evaluative audience should enhance performance for a simple, well-learned task such as rope pulling, and, although there is little supportive evidence, it seems reasonable that the larger the audience, the greater the enhancement (Martens & Landers, 1969; Seta, Paulus, & Schkade, 1976). Thus, it is not clear whether there was a reduced effort put forth by group members because they believed other people were pulling with them, or an increase in the effort exerted by individuals because they believed other people were watching them. In Experiment 2, therefore, we arranged to hold the size of the audience constant, even while varying the number of people working together.

Method

Six groups of six male undergraduate volunteers heard the following instructions:

> In our experiment today we are interested in the effects of sensory feedback on the production of sound in social groups. We will ask you to produce sounds in groups of one, two, or six, and we will record the sound output on the sound-level meter that you can see up here in front. Although this is not a competition and you will not learn your scores until the end of the experiment, we would like you to make your sounds as loud as possible. Since we are interested in sensory feedback, we will ask you to wear blindfolds and earphones and, as you will see, will arrange it so that you will not be able to hear yourself as you shout.
>
> We realize it may seem strange to you to shout as loud as you can, especially since other people are around. Remember that the room is soundproofed and that people outside the room will not

be able to hear you. In addition, because you will be wearing blindfolds and headsets, the other participants will not be able to hear you or to see you. Please, therefore, feel free to let loose and really shout. As I said, we are interested in how loud you can shout, and there is no reason not to do your best. Here's your chance to really give it a try. Do you have any questions?

Once participants had donned their headsets and blindfolds, they went through a series of 13 trials, in which each person shouted four times in a group of six, once in a group of two, and once by himself. Before each trial they heard the identification letters of those people who were to shout.

Interspersed with these trials were 12 trials, two for each participant, in which the individual's headset was switched to a separate track on the stereophonic instruction tape. On these trials, everybody else was told that only the focal person should shout, but that individual was led to believe either that one other person would shout with him or that all six would shout.

Thus, each person shouted by himself, in actual groups of two and six, and in pseudogroups of two and six, with trials arranged so that each person would have approximately equal rest periods between the trials on which he performed. Each trial was preceded by the specification of who was to perform. The yells were coordinated by a tape-recorded voice counting backwards from three, followed by a constant 90-dB 5-sec recording of the sound of six people shouting. This background noise made it impossible for performers to determine whether or how loudly other people were shouting, or, for that matter, to hear themselves shout. Each trial was terminated by the sound of a bell. This sequence of 25 trials was repeated three times, for a total of 75 trials, in the course of which each subject shouted 24 times.

As in Experiment 1, the data were transformed into dynes/cm^2 and subjected to analyses of variance, with the group as the unit of analysis and each score based on the average output per person. Two separate 3×3 analyses of variance with group size (1,2,6) and trial block (1–3) were run, one on the output of trials in which groups actually shouted together, and one on the pseudogroup trials in which only one person actually shouted.

Results

Overall, participants shouted with considerably more intensity in Experiment 2 than in Experiment 1, averaging 9.22 dynes/cm^2 when shouting alone, as compared to 4.73 dynes/cm^2, $t(12) = 4.05$, $p < .01$. There are several plausible reasons for this difference. The new rationale involving the effects of reduced sensory feedback may have interested

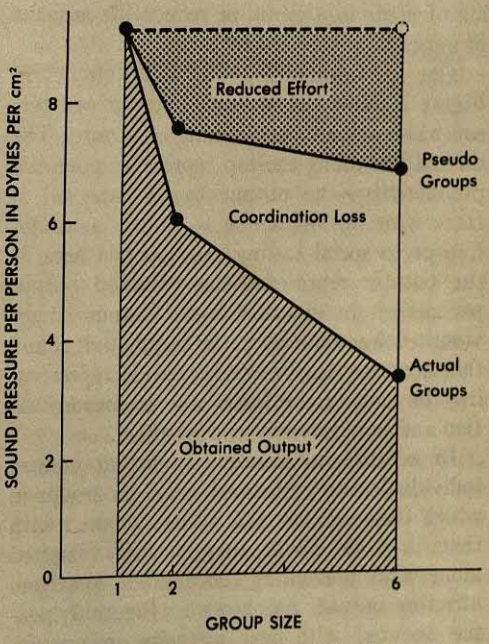

Figure 2. Intensity of sound produced per person when cheering in actual or perceived groups of 1, 2, and 6, as a result of reduced effort and faulty coordination of group efforts, Experiment 2.

or challenged individuals to perform well. The constant 90-dB background noise may have led people to shout with more intensity, just as someone listening to music through headphones will often speak inappropriately loudly (the Lombard reflex). The performers may have felt less embarrassed because the room was soundproof and the others were unable to see or hear them. Finally, through eliminating the possibility of hearing each other, individuals could no longer be influenced by the output of the others, thereby lifting the pressure of social conformity.

As in Experiment 1, as the number of actual performers increase, the total sound output also increased, but at a slower rate than would be expected from the sum of the individual outputs. Actual groups of two shouted at only 66% of capacity, and groups of six at 36%, $F(2, 10) = 226$, $p < .001$. The comparable figures for Experiment 1 are 71% and 40%. These similarities between experiments suggest that our procedural changes, even though they made people unable to hear or see each other, did not eliminate their feel-

ing of being in a group or reduce the amount of incoordination or social loafing.

The line connecting the solid circles in Figure 2 shows the decreased output per person when actually performing in groups. The dashed line along the top represents potential productivity—the output to be expected if there were no losses due to faulty coordination or to social loafing. The striped area at the bottom represents the obtained output per person in actual groups. Output is obviously lower than potential productivity, and this decrease can be considered as representing the sum of the losses due to incoordination and to reduced individual effort.

In addition to shouting in actual groups, individuals also performed in pseudogroups in which they believed that others shouted with them but in which they actually shouted alone, thus preventing coordination loss from affecting output. As shown in Figure 2, people shouted with less intensity in pseudogroups than when alone, $F(2, 10) = 37.0$, $p < .0001$. Thus, group size made a significant difference even in pseudogroups in which coordination loss is not a factor and only social loafing can operate.

When performers believed one other person was yelling, they shouted 82% as intensely as when alone, and when they believed five others to be yelling, they shouted 74% as intensely. The stippled area defined at the top of Figure 2 by the data from the pseudogroups represents the amount of loss due to social loafing. By subtraction, we can infer that the white area of Figure 2 represents the amount of loss due to faulty coordination. Since the latter comprises about the same area as the former, we can conclude that, for shouting, half the performance loss decrement is due to incoordination and half is due to social loafing.

Discussion

Despite the methodological differences between Experiments 1 and 2, both experiments showed that there is a reduction in sound pressure produced per person when people make noise in groups compared to when alone. People in Experiment 1 applauded and cheered in full view of each other, with all the excitement, embarrassment, and conformity that goes along with such a situation. In Experiment 2, no one could see or hear any other person. Only the experimenters could see the people perform. And finally, the rationale changed drastically, from the experimenters' interest in "judgments of how much noise people make in social settings" to their interest in "the effects of sensory feedback on the production of sound in social groups." Yet, despite differences in the task characteristics and supposed purpose, the two studies produced similar results. This points to the robust nature of both the phenomenon and the paradigm.

General Discussion

Noise Production as Group Performance

Although we do not usually think about it that way, making noise can be hard work, in both the physical and the psychological sense. In the present case, the participants were asked to produce sound pressure waves, either by rapidly vibrating their laryngeal membranes or by vigorously striking their hands together. Although superficially similar in consequence, this task should not be confused with more normal outbreaks of shouting and clapping that occur as spontaneous outbursts of exuberant expressiveness. Our participants shouted and clapped because we asked them to, not because they wanted to.

This effortful and fatiguing task resulted in sound pressure waves, which, although invisible, can be easily and accurately measured in physical units that are proportional to the amount of work performed. The making of noise is a useful task for the study of group processes from the standpoint both of production and of measurement—people are practiced and skilled at making noise and can do so without the help of expensive or cumbersome apparatus, and acoustics and audio engineering are sufficiently advanced to permit sophisticated data collection. We seem to have found a paradigm wherein people get involved enough to try hard and become somewhat enthusiastic, yet the task is still effortful

enough so that they loaf when given the opportunity.

The Causes of Social Loafing

The present research shows that groups can inhibit the productivity of individuals so that people reduce their exertions when it comes to shouting and clapping with others. Why does this occur? We suggest three lines of explanation, the first having to do with attribution and equity, the second with submaximal goal setting, and the third with the lessening of the contingency between individual inputs and outcomes.

1. *Attribution and equity.* It may be that participants engaged in a faulty attribution process, leading to an attempt to maintain an equitable division of labor. There are at least three aspects of the physics and psychophysics of producing sound that could have led people to believe that the other persons in their group were not working as hard or effectively as themselves. First, individuals judged their own outputs to be louder than those of the others, simply because they were closer to the sound source. Second, even if everyone worked to capacity, sound cancellation would cause group outputs to seem much less than the sum of their individual performances. Finally, the perception of the amount of sound produced in a group should be much less than the actual amount—growing only as the .67 power of the actual amount of sound, according to Stevens's psychophysical power law (1975).

These factors may have led individuals to believe that the other participants were less motivated or less skillful than themselves—in short, were shirkers or incompetents. Thus, differences in the perception of sound production that were essentially the result of physical and psychophysical processes may have been mistakenly attributed to a lack of either skill or motivation on the part of the others, leading individuals to produce less sound in groups because there is no reason to work hard in aid of shirkers or those who are less competent.

This process cannot explain the results of Experiment 2, since the capacity to judge the loudness of one's own output, much less that of others, was severely impaired by the 90-dB background masking noise used to signal the trials. However, rather than "discovering" social loafing while participating in the experiment, the participants may have arrived with the preexisting notion that people often do not pull their own weight in groups. Thus, despite being unable to hear or see one another, lack of trust and the propensity to attribute laziness or ineptitude to others could have led people to work less hard themselves.

2. *Submaximal goal setting.* It may be that despite our instructions, participants redefined the task and adopted a goal, not of making as much noise as possible, but merely of making enough noise or of matching some more or less well-defined standard. Individuals would clearly expect it to be easier to achieve this goal when others are helping, and might work less hard as a consequence. This, of course, would change the nature of noise production from what Steiner (1972) would term a *maximizing* task to an *optimizing* task. A maximizing task makes success a function of how much or how rapidly something is accomplished. For an optimizing task, however, success is a function of how closely the individual or group approximates a predetermined "best" or correct outcome. If participants in our experiments perceived sound production as an optimizing rather than a maximizing task, they might feel the optimal level of sound output could be reached more easily in groups than alone, thereby allowing them to exert less effort.

The participants in Experiment 2 could hear neither themselves nor others and would not be able to determine whether their output was obnoxious or to develop a group standard for an optimal level. Furthermore, in both experiments, the experimenters reiterated their request to yell "as loud as you can, every time," over and over again. Before the first trial they would ask the group how loud they were supposed to yell. In unison, the group would reply, "As loud as we can!" We think it unlikely that participants perceived the task to be anything other than maximizing.

3. *Lessened contingency between input and*

outcome. It may be that participants felt that the contingency between their input and the outcome was lessened when performing in groups. Individuals could "hide in the crowd" (Davis, 1969) and avoid the negative consequences of slacking off, or they may have felt "lost in the crowd" and unable to obtain their fair share of the positive consequences for working hard. Since individual scores are unidentifiable when groups perform together, people can receive neither precise credit nor appropriate blame for their performance. Only when performing alone can individual outputs be exactly evaluated and rewarded.

Let us assume that group members expect approval or other reward proportional to the total output of a group of n performers, but that since individual efforts are indistinguishable, the reward is psychologically divided equally among the participants, each getting $1/n$ units of reward. Under these assumptions, the average group, if it performed up to capacity and suffered no process loss, could expect to divide up n times the reward of the average individual, resulting in each member's getting $n \times 1/n$, or n/n, units of reward, the same amount as an individual.

Although the total amount of reward may be the same, the contingency on individual output is not. Any given individual under these assumptions will get back only one nth of his own contribution to the group; the rest will be shared by the others. Even though he may also receive unearned one nth of each other person's contribution, he will be tempted, to the extent that his own performance is costly or effortful, to become a "free rider" (Olson, 1965). Thus, under these assumptions, if his own performance cannot be individually monitored, an individual's incentive to perform should be proportional to $1/n$.

Seligman (1975) has shown that animals and people become lethargic and depressed when confronted with tasks in which they have little or no control over the outcomes. Likewise, in our experiments, people may have felt a loss of control over their fair share of the rewards when they performed in groups, leading them also to become, if not lethargic and depressed, at least less enthusiastic about making lots of noise.

Since people were asked to shout both alone and in groups, they may have felt it smart to save their strength in groups and to shout as lustily as possible when scores were individually identifiable, marshalling their energy for the occasions when they could earn rewards. This line of reasoning suggests that if inputs were made identifiable and rewards contingent on them, even when in groups, it would be impossible for performers to get a free ride and they would have an incentive to work equally hard in groups of different sizes.

Social Loafing and Social Impact Theory

Each of these three lines of explanation may be described in terms of Latané's (1973) theory of social impact. If a person is the target of social forces, increasing the number of other persons also in the target group should diminish the pressures on each individual because the impact is divided among the group members. In a group performance situation in which pressures to work come from outside the group and individual outputs are not identifiable, this division of impact should lead each individual to work less hard. Thus, whether the subject is dividing up the amount of work he thinks should be performed or whether he is dividing up the amount of reward he expects to earn with his work, he should work less hard in groups.

The theory of social impact further stipulates the form that the decrease in output should follow. Just as perceptual judgments of physical stimuli follow power functions (Stevens, 1957), so also should judgments of social stimuli, and the exponent of the psychosocial power function should have an exponent of less than one, resulting in a marginally decreasing impact of additional people. Thus, social impact theory suggests that the amount of effort expended on group tasks should decrease as an inverse power function of the number of people in the group. This implication cannot be tested in Experiment 1 or with the actual groups of Experiment 2, inasmuch as coordination loss is confounded with social loafing. However, a power function with an

exponent of −.14 accounted for 93% of the variance for the pseudogroups of Experiment 2. It appears that social impact theory provides a good account of both the existence and the magnitude of social loafing.

The Transsituational and Transcultural Generality of Social Loafing

The present research demonstrates that performance losses in groups occur with tasks other than rope pulling and with people other than prewar German workers. There are, in addition, other instances of experimental research that demonstrate similar cases of social loafing. For example, Marriott (1949) and Campbell (1952) have shown that factory workers produce less per person in larger groups than in smaller ones. Latané and Darley (1970) have found that the likelihood that a bystander will intervene in a situation in which someone requires assistance is substantially reduced by the addition of other bystanders who share in the responsibility for help. Wicker (1969) has found that the proportion of members taking part in church activities is lower in large than in small churches, presumably because the responsibility for taking part is more diffuse. Similarly, Petty, Harkins, Williams, and Latané (1977) found that people perceived themselves as exerting less cognitive effort on evaluating poems and editorials when they were among groups of other unidentifiable evaluators than when they alone were responsible for the task.

These experimental findings have demonstrated that a clear potential exists in human nature for social loafing. We suspect that the effects of social loafing have far-reaching and profound consequences both in our culture and in other cultures. For example, on collective farms (kolkhoz) in Russia, the peasants "move all over huge areas, working one field and one task one day, another field the next, having no sense of responsibility and no direct dependence on the results of their labor" (Smith, 1976, p. 281). Each peasant family is also allowed a private plot of up to an acre in size that may be worked after the responsibility to the collective is discharged. The produce of these plots, for which the peasants are individually responsible, may be used as they see fit. Although these plots occupy less than 1% of the nation's agricultural lands (about 26 million acres), they produce 27% of the total value of Soviet farm output (about $32.5 billion worth) (Yemelyanov, 1975, cited in Smith, 1976, p. 266). It is not, however, that the private sector is so highly efficient; rather, it is that the efficiency of the public sector is so low (Wädekin, 1973, p. 67).

However, before we become overly pessimistic about the potential of collective effort, we should consider the Israeli kibbutz, an example that suggests that the effects of social loafing can be circumvented. Despite the fact that kibbutzim are often located in remote and undeveloped areas on the periphery of Israel to protect the borders and develop these regions, these communes have been very successful. For example, in dairying, 1963 yields per cow on the kibbutz were 27% higher than for the rest of Israel's herds, and in 1960 yields were 75% higher than in England. In 1959, kibbutz chickens were producing 22% of the eggs with only 16% of the chickens (Leon, 1969). The kibbutz and the kolkhoz represent the range of possibilities for collective effort, and comparisons of these two types of collective enterprise may suggest conditions under which per person output would be greater in groups than individually.

Social Loafing as a Social Disease

Although some people still think science should be value free, we must confess that we think social loafing can be regarded as a kind of social disease. It is a "disease" in that it has negative consequences for individuals, social institutions, and societies. Social loafing results in a reduction in human efficiency, which leads to lowered profits and lowered benefits for all. It is "social" in that it results from the presence or actions of other people.

The "cure," however, is not to do away with groups, because despite their inefficiency, groups make possible the achievement of many goals that individuals alone could not

possibly accomplish. Collective action is a vital aspect of our lives: From time immemorial it has made possible the construction of monuments, but today it is necessary to the provision of even our food and shelter. We think the cure will come from finding ways of channeling social forces so that the group can serve as a means of intensifying individual responsibility rather than diffusing it.

Template Matching: A Proposal for Probing the Ecological Validity of Experimental Settings in Social Psychology

Daryl J. Bem
Cornell University

Charles G. Lord
Stanford University

The question of ecological validity—Do people behave in real life as they behave in our laboratories?—is central to experimental social psychology. The template-matching technique is introduced as a way to explore such validity. First, each laboratory behavior is characterized by a *template*, a personality description (Q sort) of the hypothetical ideal person most likely to display that behavior. These templates characterize subjects' potential behaviors inside the laboratory. Next, Q-sort personality descriptions of the subjects are obtained from their peers; these characterize the subjects' behaviors outside the laboratory. Evidence for the ecological validity of the laboratory setting is then sought in the match between these two sets of data. Using this technique, support was found for the ecological validity of the mixed-motive game, a widely used laboratory paradigm whose validity is often questioned. The heuristic use of Q-sort data to draw clinical portraits of the subjects is also illustrated.

Do people behave in real life as they behave in our experimental laboratories? This question, the question of ecological validity, is central to experimental social psychology, and the possibility that the answer might be *no* is central to the field's recent crisis of confidence (e.g., McGuire, 1973; Ring, 1967). Not surprisingly, the strongest doubts are provoked by the field's more dramatic experiments: Is there really a plausible analogue between a subject's obediently delivering shocks to a fellow subject in Milgram's laboratory and an Eichmann's obediently delivering Jews to their deaths in Nazi Germany (Baumrind, 1964; Milgram, 1974; Orne & Holland, 1968)? Does a Zimbardo prison with college students playing the roles of guards and prisoners really capture any of the functional properties of actual incarceration (Banuazizi & Movahedi, 1975; Haney, Banks, & Zimbardo, 1973)? But even the field's more mundane experimental paradigms must bear the same burden of proof. Do the cooperative and competitive choices of subjects in the Prisoner's Dilemma game, for example, have any parallels with the cooperative and competitive choices of individuals in the real world—let alone the foreign policy choices of nation states? The concern is not new: Even well before the current crisis, Carl Hovland was agonizing over the fact that laboratory and field studies of persuasive communication produced widely divergent results (Hovland, 1959).

Investigators have usually attempted to establish the external validity of their laboratory procedures in two basic ways. The first strategy, often proposed but rarely performed, is to conduct conceptually parallel laboratory experiments and field studies in tandem, in order to confirm the assumed

The authors are grateful to Spencer Kagan and his colleague George Knight for providing template weights. They also wish to thank their own colleagues Craig Anderson, Marjorie Horton, Dennis Jennings, David Maxfield, and Ken Monteiro for providing template weights. For assistance in conducting the study, they would like to thank Greg Eger, Pat Flinn, and Rod Hubbard.

All Q-sort materials used in this research are available from Consulting Psychologists Press, 577 College Avenue, Palo Alto, California 94306.

isomorphism directly. The second strategy is to demonstrate the construct validity of the laboratory-assessed concepts, to show that the behavior relates to other variables as the theory says it should. For example, one's faith in the ring-toss game as a situation that elicits achievement motivation is bolstered by findings that individuals high on the motive stand a moderate distance from the peg as the theory of achievement motivation implies (McClelland, 1958). Similarly, one's confidence in a paradigm's external validity is enhanced if individual difference variables relate to the laboratory behaviors in theoretically compelling ways.

The Template-Matching Technique

In this article, we propose a novel extension of the individual-differences approach to assessing the degree to which subjects' behaviors in the laboratory match their behaviors in everyday life. It is called the template-matching technique, a general method introduced by Bem and Funder (1978) for characterizing situations in the language of personality description. Applied to the problem of ecological validity, the technique consists of two basic steps. First, each conceptually distinct behavior in the laboratory setting under investigation is characterized by a *template*, a personality description of the hypothetical ideal person who is most likely to display the designated behavior in that situation. These templates serve to characterize the potential behaviors of subjects inside the laboratory. Second, personality descriptions of the subjects are obtained from close acquaintances; these descriptions characterize the subjects' behaviors outside the laboratory. The ecological validity of the laboratory setting, then, is sought in the match between these two sets of data. Specifically, the model predicts that the description of the individual's personality will match most closely the template that characterizes the behavior he or she actually displays in the laboratory. A complete discussion of the procedure is provided by Bem and Funder (1978), who have applied it to the delay-of-gratification situation and the forced-compliance experiment, demonstrating how it can be used to pinpoint sources of cross-situational inconsistency and to test rival theories of psychological phenomena.

The Mixed-Motive Game

To illustrate the utility of the template-matching technique for addressing the issue of ecological validity, we have chosen to apply it to one of the most frequently used—and frequently criticized—experimental paradigms in social psychology, the mixed-motive game (e.g., the Prisoner's Dilemma game). It will be recalled that in this procedure, two subjects are required simultaneously to make a series of decisions independently of each other and with no communication between them. The payoff to each subject is contingent on both of their choices. Thus in the Prisoner's Dilemma game, the most familiar of the mixed-motive games, when both subjects select the *cooperative* response, their joint payoff is high; when both select the *competitive* response, their joint payoff is low; when one subject chooses the cooperative response and the other the competitive response, the latter (the *defector*) earns points or money at the expense of the cooperator. The mixed-motive game is a particularly appropriate test case here, not only because it has been extensively used, but also because the debate between its proponents (e.g., Kelley et al., 1970) and its critics (e.g., Knox & Douglas, 1971; Nemeth, 1972; Pruitt, 1967) nicely epitomizes the field's more general concern with the issue of ecological validity.

Most of the studies using the mixed-motive game are concerned not with its external validity but with the internal structure of the situation, the ways in which a subject's playing strategy varies as a function of the payoff matrix, communication variables, and preprogrammed features of the opponent's strategy. (See, for example, reviews by Nemeth, 1972, and Oskamp, 1971. See also Kuhlman & Marshello, 1975.) Such studies yield an internally consistent picture of cooperation and competition within the paradigm but provide very little in the way of independent evidence for its ecological validity.

There appear to be no studies that directly compare a laboratory experiment and a field

situation, and most of the studies that do bear upon the issue of external validity are those that explore group or individual differences. For example, army cadets are more competitive in mixed-motive games than Berkeley students (Pilisuk, Kiritz, & Clampitt, 1971); individuals high on the need for power are more competitive than those low on this motive (Terhune, 1968); isolationists are more competitive than internationalists (McClintock, Harrison, Strand, & Gallo, 1963); high authoritarians are more competitive than low authoritarians (Wrightsman, 1966); externals are more competitive than internals (Tiller, 1970). And, in a study that goes beyond the simple cooperative–competitive dichotomy by utilizing the *decomposed* versions of mixed-motive games introduced by Messick and McClintock (1968), it was found that subjects who systematically attempted to maximize the joint gain of both players (called J's) scored higher on the Affiliation and Intraception scales but lower on the Aggression scale of the Edwards Personal Preference Schedule (Edwards, 1959) than did subjects who attempted to maximize their own gain (O's) or subjects who attempted to maximize their gain relative to the other person (R's) (Bennett & Carbonari, 1976).

In the study reported here, we also used the decomposed mixed-motive games. Specifically, we constructed templates of three hypothetical persons: the ideal J, the ideal O, and the ideal R. Each subject in the actual experiment was then classified on the basis of his or her responses as a J, an O, or an R, and it was predicted that the subject's similarity to the corresponding template would be higher than his or her similarity to the templates characterizing the two alternative strategies.

Method

The Mixed-Motive Game and Its Decomposition

In a mixed-motive game, two subjects are isolated from one another and required simultaneously to select from Alternatives A and B in the payoff matrix shown in Table 1. This matrix is an example of the Prisoner's Dilemma game in which joint cooperation (A responses) earns the players the maximum joint payoff, joint competition (B responses) yields minimum joint payoff, and *defection* to the competitive response (B) earns the defector maximum payoff when the other player selects the cooperative response (A).

Table 1
Payoff Matrix for the Prisoner's Dilemma Game

Other person's choice	Your choice: A		Your choice: B	
A	You earn Other earns	100 100	You earn Other earns	110 70
B	You earn Other earns	70 110	You earn Other earns	80 80

Every mixed-motive game can also be decomposed into a situation in which the subject makes his or her own choices without direct simultaneous reference to the other subject's behavior. For example, the full-matrix mixed-motive game decomposes into the following decision alternatives for such a subject:

	Your choice: A	Your choice: B
You earn	60	70
Other earns	40	10

Here the subject chooses between A and B while being told that the other subject is making the same choice concurrently. Note that if the subject chooses Alternative A, he or she assigns 60 points to the self and 40 points to the other subject; if he or she chooses Alternative B, 70 points are assigned to the self and 10 points to the other subject. The game is isomorphic to the full-matrix version because if both subjects select Alternative A, each earns 100 points; if both select B, each earns 80 points; and if one selects A and the other selects B, the former earns 70 points and the latter earns 110 points. Thus the two games are formally equivalent, but the decomposed game is played without trial-by-trial feedback, and it focuses attention on each player's individual strategy, unconfounded by two-person interactions. Note, for example, that a subject who wishes to maximize the joint outcome of both players will choose Alternative A, whereas a subject who wishes to maximize his or her own payoff will select Alternative B. The elegance of this feature is best illustrated by the Triple Dominance game in which subjects choose from among three alternatives:

	Your choice: A	Your choice: B	Your choice: C
You earn	40	50	40
Other earns	40	20	0

Note that each alternative satisfies one, and only one, of the three strategies (J, O, or R) discussed earlier. The subject who selects Alternative A assigns 40 points to the self and 40 points to the other person, thus maximizing the *joint* return for both players (80 points versus 70 or 40 points for the other alternatives); the subject who chooses Alternative B assigns 50 points to the self, thereby maximizing his or her *own* return; and the subject who chooses Alternative C assigns 40 points to the self and 0 points to the other person, maximizing his or her return *relative* to the other person (40 points versus 0 or 30 points).

The Prisoner's Dilemma game and the Triple Dominance game are but two of the possible mixed-motive games that can be used. (See, for example, Kuhlman & Marshello, 1975.)

Constructing the Templates

To operationalize the template concept, Bem and Funder (1978) employ the Q-sort technique, utilizing a modification of the California Q set of items devised by Block (1961/1978). The Q set consists of 100 descriptive personality statements (e.g., "behaves in a giving way toward others"), which are sorted by an assessor into nine categories ranging from the least to the most characteristic of the person being described; each item thus receives a score from 1 to 9. Two Q sorts can be compared with one another by simply computing a Pearson product-moment correlation across the items, thus expressing directly and quantitatively the degree of similarity between the two profiles. Similarly, if one has constructed a Q sort of some hypothetical ideal personality (our template), one can correlate the Q sorts of actual individuals with this idealized sort in order to assess their similarities to the ideal type.[1]

As noted above, the Q sort of an individual is obtained by having an assessor actually sort the 100 items into nine categories. Constructing a template, however, requires a different method for assigning numerical values to the items because only a small number of items will be relevant to any particular template. Accordingly, Bem and Funder (1978) constructed templates by "adjusting" the composite Q sort of the entire subject sample according to the following formula:

$$Q_i = M_i + w_i\sigma_i$$

where Q_i is the adjusted or template value of the ith item, M_i and σ_i are the mean and standard deviation, respectively, of the ith item for the subject sample as a whole, and w_i is a weighting factor that reflects the relevance of the ith item to the criterion behavior being characterized.

Suppose, for example, that we wish to construct a template of the person who pursues the J strategy, the strategy that maximizes the joint return of both players. The Q item "is physically attractive" is conceptually irrelevant to this behavior, and accordingly, it is assigned a relevance weight (w_i) of zero. The adjusted value of this item in the template, then, simply becomes the mean of the item in the subject sample. But now consider the item "behaves in a giving way toward others," which would seem relevant to the behavior implied by the J strategy. If we assign this a weight of, say, +2, then the template value of this item will be adjusted upward from the sample mean by two standard deviations, and—the model predicts—the resulting template will be more similar to the Q sorts of individuals who pursue the J strategy than to the Q sorts of individuals pursuing the alternative strategies. A complete discussion of this template-construction algorithm will be found in Bem and Funder (1978).

In the present study, we constructed the templates by recruiting five graduate students in psychology to serve as judges. They were supplied with a written description of the three strategies along with the illustrative Triple Dominance game shown above and the complete list of Q-sort items. Each judge went through the list and gave an integer rating to each item, ranging from −2 ("very uncharacteristic of a person following this strategy") through 0 ("not relevant; neither characteristic nor uncharacteristic of the person following this strategy") to +2 ("very characteristic of the person following this strategy"). For example, the item "behaves in a giving way toward others" received a mean rating of +1.6 for the J strategy, and the item "is power oriented; values power in self and others" received a mean rating of +1.2 for the R strategy, the strategy in which subjects attempt to maximize their earnings relative to the other person. The judges were explicitly directed not to play personality theorist, not to speculate about remote personality correlates of the behavior, but rather to judge only whether an item might or might not characterize the behavior involved in the strategy itself. The judges completed this procedure for each of the three strategies. The mean rating given each item by the five judges then became the relevance weight (w_i) for that item in the template-generating algorithm described previously. Separate templates were constructed for each sex by using the same set of weights (w_is) but the separate means and standard deviations (M_is and σ_is) for each sex. This procedure, then, yielded a set of templates for the

[1] Even though this index of similarity is computed like a product-moment correlation, it cannot be treated like one statistically. For example, there is no reason to expect the correlation between any two Q sorts selected at random to have an expected value of zero. Moreover, the magnitude of the correlation is a function of factors other than the component of template-specific similarity in which we are interested. (See Bem & Funder, 1978.) To avoid any confusion on this issue, we routinely convert these similarity scores to standardized T scores with means of 50 and standard deviations of 10.

situation, each characterizing one of the three "pure" strategies that could be pursued.

For purposes of comparison, a second set of templates was constructed by enlisting the aid of Spencer Kagan, an investigator who has worked extensively with the decomposed mixed-motive games and who, in fact, distinguishes not 3, but 16 distinct strategies in his own work (Kagan, 1972, 1977). Moreover, because Kagan is trained as a clinician, we asked him to supply a set of weights (w_is) for the three strategies by drawing as heavily as he wished on his accumulated experience and clinical intuitions, instructions quite different from the conservative and restrictive guidelines we imposed upon our graduate-student judges.

The Experiment

Forty-eight male and 44 female Stanford University students who had previously provided self Q sorts in an unrelated setting were recruited to participate in a 1-hr "decision-making" experiment. For their participation, they received experimental credit points in introductory psychology as well as the money they earned during the experiment. In the experimental session, four subjects of the same sex were seated in separate experimental booths and told that they would be anonymously paired with each of the other subjects in turn and asked to make a series of decisions. In fact, the subjects did not actually play against one another; rather, they played simultaneously against a preprogrammed sequence of decisions throughout the experiment. They then made choices on 24 decomposed mixed-motive games with no feedback concerning the "other subject's" decisions. Each payoff matrix was projected on a screen which could be seen by all subjects from their separate booths. They then played 48 full-matrix mixed-motive games (allegedly 16 with each of the other three subjects in turn) with the usual trial-by-trial feedback about the joint payoff. After the session, they were debriefed and paid $2, the amount they would have earned with optimal play and maximally cooperative opponents.

During the following academic quarter, we contacted 10 subjects who had systematically adopted the J strategy, 10 subjects who had adopted the O strategy, and the entire sample of 10 subjects who had adopted the R strategy during the experiment. Each group contained 5 males and 5 females. All these subjects gave us permission to obtain confidential Q sort descriptions of them from one of their roommates. The roommates came to our laboratory and were paid $2 to complete the Q sorts; they were not told about the subjects' participation in our experiment the previous quarter. (Since students in introductory psychology participate in several studies, it is unlikely that these roommates knew about the experiment or its relation to the information they were providing.) Finally, the experimenters in the several phases of the study were always blind with respect to all other information about the subjects and the study.

Results and Discussion

The first step in the analysis of the data was to classify each subject as a J, an O, or an R, according to the criterion that he or she must have selected 50% or more of the choices compatible with that strategy on each of the four types of decomposed games. Under this criterion, we classified 36% of our subjects as J's, 39% as O's, and 11% as R's, leaving 14% unclassified. This grouping contains relatively fewer R's and unclassified subjects than reported by Kuhlman and Marshello (1975), who used the same classification criterion.

We next confirmed that behavior on the decomposed games does, in fact, predict behavior on the more familiar full-matrix games employed in most previous studies. For example, those who adopted the strategy of trying to maximize the joint return of both themselves and the other person in the decomposed games (J's) selected the cooperative response on full-matrix games 71% of the time; those who adopted the strategy of maximizing their own return (O's) selected the cooperative response 57% of the time; and those who adopted the strategy of trying to maximize their return relative to the other subject (R's) selected the cooperative response 31% of the time. This result is highly significant, $F = 20.47$, $p < .001$, with no overlap between the 95% confidence intervals for the three groups. Clearly, then, we can generalize from the decomposed games to the full-matrix games, a fact that has not previously been established using a variety of full-matrix mixed-motive games (cf. Kuhlman & Marshello, 1975).

Assessing Ecological Validity

As we noted earlier, the roommates' Q sorts of our subjects characterize their behaviors outside the laboratory, and the templates characterize their behaviors within the laboratory. Accordingly, the ecological validity of the laboratory situation is sought in the match between these two sets of data. Specifically, we predict that each subject's roommate Q sort will be more similar to the template characterizing his or her adopted

strategy in the laboratory than to the templates characterizing the two alternative strategies.

To test this hypothesis, the subjects' roommate Q sorts were correlated with each of the three sex-appropriate templates in turn; and for each template, these correlations were then converted to standardized T scores with means of 50 and standard deviations of 10 so that all templates would have the same baseline, that is, would equally characterize the average or composite subject. (Also see Footnote 1.) All analyses were then conducted on these standardized template-similarity scores.

The results show that our subjects' roommate Q sorts are, in fact, more similar to the templates characterizing their actual playing strategies than they are to the alternative templates (52.2 vs. 48.9), $t(29) = 2.33$, $p < .025$, one-tailed. Moreover, this effect is consistent across subjects: 22 of the 30 difference scores were positive, $z = 2.37$, $p = .009$, by a one-tailed sign test. The templates generated by our clinical expert, Spencer Kagan, were similarly successful (52.5 vs. 48.8), $t(29) = 2.63$, $p < .01$, one-tailed, with 21 of the 30 difference scores positive, $z = 2.01$, $p = .022$, one-tailed. The template-matching technique has thus provided one kind of support for the ecological validity of mixed-motive games as analogues to real-world situations. As seen by their peers, our subjects behave outside the laboratory as we saw them behave within it. The relationship between this kind of evidence and the full assessment of ecological validity will be discussed later.[2]

Clinical Portraits of the Subjects

Although it is the template-matching techniques that provide the formal mechanism for testing hypotheses about situations, it is the Q-sort information that has the most heuristic potential for revealing the functional properties of the setting and probing the meaning of the behaviors observed (Bem & Funder, 1978). In particular, Q sorts draw clinical portraits of the subjects and identify those attributes that discriminate one type of subject from another. The following descriptions are based upon the data presented in detail in the Appendix (Table A1). On each Q item, each subject type is contrasted with its same-sex complement (e.g., male J's vs. male O's and R's combined), using the error term from the one-way analysis of variance on the item. This is done separately for the roommate Q sorts and the self-sorts of the subjects. Within each subject type, the item is also tested to see if the roommates and the subjects disagree significantly.

Again, it is the heuristic value of this analysis that we wish to emphasize; the statistical tests should be used only as rough guidelines. First, we conducted a separate analysis on each item; some of the significant contrasts may have emerged by chance. Second, the contrasts comparing each subject type against its complement are not orthogonal; if a group is significantly higher than its complement on an item, one or both of the other types are likely to show up, nonindependently, as significantly lower than their complements on that same item. And finally, even though a subject type might be significantly higher than its complement on a particular item, this does not necessarily mean that the item is descriptive of the type in absolute terms. (The absolute standing of an item can be inferred roughly from Table A1, which lists the items in rank order for the sample as a whole, based on the roommates' sorts. Thus the top items are those that are most descriptive of the subject sample; the bottom items are those least descriptive of the sample.)

With these caveats in mind, we can venture into the clinical thicket of Table A1. Since the complete data base is provided, the reader is free to agree or disagree with our interpretations and to venture more or less boldly than we shall do.

The J's. The J strategy is the cooperative or even altruistic strategy that maximizes the players' joint return as well as the other player's return. Relative to the complement,

---

[2] No significant results are obtained if the self-sorts rather than the roommates' sorts are used in the template-matching analysis. We shall see the reason for this in what follows.

the male J is described by his roommate as thinking in unusual ways, being repressive, not arousing liking and acceptance in people nor having social poise, not being gregarious, and not being particularly interesting. Relative to the complement, the male J describes himself as being introspective, concerned with philosophical problems, and, feeling a lack of personal meaning in life, and he agrees with his roommate that he thinks and associates ideas in unusual ways. He also sees himself as having relatively little social poise and as being less masculine and less power oriented than the complement males consider themselves to be. He doesn't think he is as repressive as his roommate does, however. These various findings are reminiscent of the Bennett and Carbonari (1976) finding that J's score higher on the Intraception scale but lower on the Aggression scale of the Edwards Personal Preference Schedule than the complement groups do and lower on the Heterosexual scale than the R's do.

The female J looks a bit more rigid than the male J. She is described by her roommate as being concerned with philosophical problems, but she is also seen as moralistic, fastidious, fussy about minor things, and having persistent, preoccupying thoughts. She describes herself as being basically distrustful of people in general, but this is only in contrast to the complement groups' self-ratings; the item still falls well into the uncharacteristic end of her self Q sort. In general, her roommate sees her less positively than she sees herself, rating her significantly higher on such items as "delays gratification unnecessarily," "concerned with own bodily functions," "thin-skinned; sensitive to criticism," "would be disorganized under stress," and "has persistent, preoccupying thoughts." Her roommate rates her significantly lower on the items "is cheerful," "enjoys aesthetic impressions," and "behaves in an assertive fashion."

In general, the J's turned out to be more withdrawn and less charming than the warm, outgoing, generous people our judges had anticipated. Their generosity in the mixed-motive games seems to spring more from an ethical or moral position—and a rather rigid one among the women—than from a spontaneous love of people. Thus, the J templates, while still characterizing the J's better than the O's or the R's, tended to err on the side of being too positive about this group. Indeed, the item "behaves in a giving way toward others," the assumed sine qua non of the J strategy, does not discriminate the J's from the other groups.

The O's. The O strategy attempts to maximize the individual's own earnings irrespective of the other player's outcomes. This was the modal strategy, being adopted by 39% of the subject sample. It also turned out to be the normative strategy in the sense that it conveys the least amount of individuating information about those who adopt it. Although there are several discriminating items in the Q sorts of the O's, they do not form any obvious clusters, nor do any of them seem particularly related to the O strategy as such. Rather, it appears that the J's and the R's define the distinctive groups in the study, with the O's constituting the residual group. The templates were least successful at capturing this group, tending to describe them as much more selfish and self-centered than they turned out to be. In fact, the O's would appear to be the roommates of choice, particularly the women, who are described as cheerful, verbally fluent, aesthetically sensitive, interpersonally consistent, and not particularly thin-skinned or fussy.

The R's. The R strategy is the most competitive in that it manages to maximize the difference between the individual's return and the other player's return, as well as to minimize the absolute return for the other player. This was the most deviant strategy in our Stanford sample of 92 subjects, and our subsample of 30 on whom we have roommate sorts contains the entire set of 5 men and 5 women who adopted it. They are deviant in their personal attributes as well.

Consider the males first. Being competitive is, of course, sex-role appropriate for men in our culture, and the male R seems to epitomize the stereotypic extraverted American male. He is assertive, masculine, socially poised, conservative, conventional, and somewhat condescending. He is not introspective, guilt ridden, anxious, or plagued by doubts

about the meaning of life. He describes himself as dependable, straightforward, and candid. (Bennett & Carbonari, 1976, found the R's to be higher on Aggression and Heterosexuality than the J's were, but not significantly different from the O's.) Such a picture may not be deviant in the larger culture, but the male R's are clearly in the minority among Stanford males, and this may explain why our study uncovered fewer R's than reported by other investigators.

The female R's are the most interesting group of all. Here is a group of women who pursue a strategy quite at variance with the sex-role stereotype of the female, and yet they describe themselves as quintessentially feminine: feminine, physically attractive, socially poised, arousing liking and acceptance in others, not condescending, and not distrustful. Their roommates do not agree, finding them instead to be aloof from people, power oriented, negativistic, tending to undermine, obstruct or sabotage, not sympathetic, considerate, or giving, and not relating to everyone in the same way. Compared to the female R's self-image, her roommate sees her as hostile, distrustful, critical, histrionic, not cheerful, not gregarious, and as having little or no insight into her own motives and behavior. The female R's and their roommates disagree significantly on 25 of the 100 Q-sort items, representing 30% of all the roommate–self discrepancies observed among the six groups. This is a proportion almost twice that expected by chance, $z = 3.22$, $p < .002$, two-tailed. All in all, the female R's present a rather chilling portrait. It is also clear why the self-sorts did not function well in the template-matching procedure. In the laboratory, we saw the women their roommates saw.

Q Sorts, Template Matching, and Ecological Validity

In our view, the major payoff from the present investigation resides in the data-rich Table A1—however unwieldy and statistically unaesthetic it may be. We believe that investigators ought to collect Q-sort data routinely even when they have no interest in individual differences per se, particularly when a new laboratory paradigm is first being developed. By examining the Q items that correlate with the behavior under investigation, one can learn an enormous amount about the subjects and the experimental setting simultaneously. (See Bem & Funder, 1978.) Although we advocate collecting Q-sort data from peers as well as from the subjects themselves, the more easily obtained self-sorts would probably suffice for many purposes. Even the ranking of Q-sort items that characterizes a subject sample as a whole provides valuable information. For example, when an experiment fails to replicate, suspicions often center upon subject-sample differences, but the sparse demographic information usually available on subject samples provides little help in assessing this possibility. In contrast, composite Q sorts of the subject samples involved would provide instant leads about the possible sources of different results patterns across seemingly identical investigations. In the present study, for example, it is clear from the composite Q sort of the sample as a whole (summarized by Table A1) that we should expect to see few R's in our mixed-motive games; Stanford students, it appears, are a rather saintly group. In the "context of discovery," there is no match for Q-sort data.[3]

The template-matching technique itself extends the heuristic utility of Q-sort data to the "context of justification" as well. In the present study, we constructed our templates on the basis of observers' ratings of the laboratory setting under investigation. We then demonstrated support for the ecological validity of mixed-motive games by showing that these templates matched peer Q-sort descriptions of the subjects' real-life behaviors outside the laboratory. Bem and Funder (1978) have demonstrated that the templates can also be constructed post hoc on the basis of the data and then cross-validated; they used

[3] The descriptive use of Q-sort data did not originate with us; it has been employed in research programs by Block and his colleagues for many years (e.g., Block, 1977; Block & Petersen, 1955). Gough (1960, 1965) makes similar use of the Adjective Check List. In our view this technique has neither received the attention it has deserved nor has its heuristic value been fully appreciated.

this variation of the technique to probe the functional properties of a delay-of-gratification situation. In a second study, they showed how templates can also be derived from formal theories, employing this variation to test rival explanations of the forced-compliance experiment against one another. The template-matching technique is thus a very general method that enables investigators to display their virtuosity at characterizing situations, and to do so in a formally legitimate way, that is, within the context of justification.

Even so, however, it is important in the present study to recognize just what successful template matching does and does not imply about the ecological validity of an experimental setting. As we have noted, it does demonstrate that the subjects are behaving in the setting as they behave in the world outside the laboratory. But this is a weak form of ecological validity. As an anonymous reviewer of this article correctly noted, the concept of ecological validity requires that the *relationships* between situational variables and the behavior in the setting replicate the *relationships* between situational variables and the behavior outside the laboratory. For example, researchers who use mixed-motive games are typically interested in how variables such as the payoff matrices, communication opportunities, and features of the opponent's playing strategies affect the subject's choices. For the game to have ecological validity in the strong sense, it must be demonstrated that these kinds of variables affect behavior in similar ways in the game's real-world counterparts. Template matching does not speak to this issue. Similarly, Hovland's (1959) lament about the divergence between laboratory and field studies of persuasion was that source and message variables did not seem to show similar effects or interactions in the two spheres. Hovland would not have been much comforted to learn that a person who is easily persuaded in the laboratory is also easily persuaded in the field.

Successful template matching, then, would appear to be a necessary but not sufficient condition for establishing the full ecological validity of a laboratory setting. Nevertheless, if the template-matching technique—or some equivalent procedure—were to be employed more widely, then we might have more confidence that people are behaving in our laboratories as they behave in real life.

Factors Affecting the Evaluation of Improvement: The Role of Normative Standards and Allocator Resources

André deCarufel
Faculty of Administration
University of Ottawa, Ottawa, Canada

In a simulated industrial setting, subjects performed a clerical task, believing that their pay was being determined by a (fictitious) peer allocator. After being treated inequitably, subjects were able to request a (fictitious) third party to review these allocations. The third party established one of two "normative" standards to govern a second series of allocations: either "fairness from now on" or "fairness now, plus compensation for the initial discrimination." Subjects subsequently received increased outcomes that matched one or the other of these standards. Concurrently, the resources available to the allocator either remained constant, increased, or decreased. The results indicated dissatisfaction despite the improvement in outcome level when the increase was felt to be inadequate relative to a normative standard and to the "social" standard formed by the allocator's own outcomes. Related hypotheses based on a relative deprivation interpretation of discontent with improvement are also presented.

Numerous social agencies and programs have been set up with the intention of improving the outcomes accruing to disadvantaged parties in our society. A particularly fascinating observation is that the recipients in these programs often become discontented with the aid and alienated from their benefactors. This pattern has been reported in a wide variety of settings, involving foreign aid recipients (Gergen & Gergen, 1971), disabled persons (Ladieu, Hanfman, & Dembo, 1947), and welfare clients (Briar, 1966). Similar observations have been reported in connection with the occurrence of riot and revolution during times of increasing prosperity (e.g., Davies, 1962; Gurr, 1970; Tocqueville, 1856). Clearly these negative responses by recipients are at variance with those envisioned by well-intentioned aid donors and social reformers. It is also clear that the improvement does not always lead to discontent, but the prevalence of these "paradoxical" responses suggests that a more thorough examination of the experience of receiving improved outcomes is in order.

A major theoretical approach to the evaluation of improvement by disadvantaged parties has its roots in the concept of relative deprivation (Crosby, 1976; Stouffer et al., 1949), which suggests that outcomes are evaluated not in objective terms but rather in relation to a subjective standard of deserving. An individual who receives less than he or she feels is deserved is hypothesized to experience a sense of injustice, which leads to cognitive and behavioral efforts to restore justice. There are at least two ways for discontent to arise in the specific case of outcome improvement (deCarufel & Schopler, 1979). If the standard of deservingness rises and falls with

This article is adapted from a doctoral dissertation submitted to the faculty of the University of North Carolina at Chapel Hill. The author wishes to thank his committee chairman, John Thibaut, and the members of his committee, John Schopler, Vaida Thompson, Andrea Sedlak, and Bernadette Gray-Little, for their advice and encouragement. Preparation of this article was facilitated by Canada Council Doctoral Fellowship W76 3918. The author wishes to thank John Thibaut, Wayne Harrison, and Chester A. Insko for their helpful comments on an earlier draft of this manuscript.

experienced outcomes, then the improvement itself may provoke feelings of entitlement. To the extent that the actual improvement lags behind these "rising expectations," discontent results. Alternatively, the parties involved may negotiate, formally or informally, a "contract" to govern subsequent allocations. Discontent arises in this case to the extent that the improvement does not match the terms of the contract.

Research and Rationale

Despite a large relative deprivation literature, few experimental studies have examined "dynamic," or changing, outcome distributions, particularly in the case of improvement over time. Two recent studies (deCarufel & Schopler, 1979; Folger, 1977) examined a simulated work setting in which subjects in the role of a worker were initially unfairly treated by a (fictitious) allocator. Folger found discontent with a subsequent improvement when it followed an expression of allocation desires by the subject ("voice") and the improvement itself failed to restore overall equality of outcomes with the allocator. Folger suggested that the voice–improvement sequence was interpreted by subjects as an acknowledgment that they deserved more pay and created the expectation that fair allocations would now follow. These hopes were, of course, dashed by the subsequent allocations.

deCarufel and Schopler examined a number of alternative interpretations based on the type of "voicing" available to subjects and also included a broader range of outcome improvements provided by the allocator within the context of overall inequality of outcomes. The results indicated increased satisfaction with the improvement when it was introduced arbitrarily by the allocator or was in response to a threat from the worker. When the "voice" took the form of an appeal to principles of fairness, an improvement providing the worker and allocator with equal outcomes in a second series of allocations led to high satisfaction. However, an objectively *larger* improvement, which gave the worker more than the allocator in the second half as a kind of "compensation" for the initial unfairness, led to no more satisfaction than no improvement at all! deCarufel and Schopler suggested that the size of the improvement may have implied different standards of fairness and set the stage for discontent. Receiving equal outcomes may have suggested a "proximal" standard of "fairness from now on." This in fact was matched, leading to high satisfaction. The compensation, however, may have implied a "distal" standard of full overall equality, which was *not* matched, leading to dissatisfaction.

Although this evidence is suggestive of the operation of rising expectations, there remain several points of ambiguity. The first is that the improvement has been interpreted not only as an increase in the subject's outcome level but also as an implicit legitimizing by the allocator of a standard of fairness for the remaining allocations. It would seem desirable to clarify the dynamics of the voice–improvement conditions with independent manipulations of the improvement and the standard. Second, the role of social comparison with the allocator's outcomes has been largely neglected in the interpretation of subjects' evaluation of the improvement. Subjects may have felt that the allocator did not meet the standard in order to maintain his/her own outcomes at a high level. Thus, a manipulation of the resources available to the allocator with which to provide various levels of improvement would be of some interest. Finally, there exists an alternative to deCarufel and Schopler's interpretation of their legitimacy conditions. This interpretation suggests that subjects may have perceived the allocator as having been overly generous in the compensation conditions. The dissatisfaction may therefore have been due to a sense of "guilt" rather than to discontent. This hypothesis, which casts doubt on the rising expectations account, also deserves experimental attention.

Hypothesis 1. If the magnitude of the improvement fails to raise the outcome level of the individual to that specified by the legitimate standard, the individual will feel dissatisfied despite the increase in his/her absolute outcome level.

This hypothesis is a direct test of the process assumed to have mediated the discontent

in the Folger (1977) and the deCarufel and Schopler (1979) studies. This hypothesis is consistent with the relative deprivation literature and with a fundamental proposition of equity theory that individuals become distressed when they find themselves participating in an inequitable relationship (Walster, Berscheid, & Walster, 1976). Discontent should be most clearly evident here in those conditions where the distal standard of full equality is legitimized but an improvement matching "only" the proximal standard is provided by the allocator. If the proximal and distal standards are referred to as the low and high standards, respectively, and the improvements matching these standards are called the small and large improvements, respectively, discontent should be evident in the high-standard–small-improvement conditions. There are two relevant comparisons. The first is the high-standard–large-improvement conditions. In this case, the distal standard is legitimized in both sets of conditions, but the small improvement does not match the standard, whereas the large one does. The statistical comparison is the simple main effect of improvement within the high-standard conditions. The second comparison is the low-standard–small-improvement conditions. Here, the magnitude of the improvement is small in both cases but it is compared to either the proximal or the distal standard. In the first case the standard is matched, whereas in the second it is not. The statistical comparison is the simple effect of standard within the small-improvement conditions. The hypothesis will be accepted only if *both* simple effects comparisons are significant.

Recall that there exists an alternative interpretation of the deCarufel and Schopler (1979) legitimacy conditions, based on the subject's experiencing guilt over the excessive magnitude of the improvement in the overcompensation cell. It has been suggested by Adams (1965) and by Walster et al. (1976) that oversufficient as well as insufficient rewards may cause uneasiness in the recipient. Several studies (e.g., Austin & Walster, 1974; Gergen, Ellsworth, Maslach, & Seipel, 1975) have in fact demonstrated a preference for equitably distributed rewards to those that were inequitable in either direction. This possibility can be examined in the present design by comparing the low-standard–large-improvement conditions, where the legitimate standard is exceeded by the improvement, with the low-standard–small-improvement conditions, where the low standard is matched, and with the high-standard–large-improvement conditions, where the high standard is matched by the improvement. The statistical comparisons are the simple main effect of improvement within the low-standard conditions and the simple main effect of standard within the large-improvement conditions, respectively. This suggestion about the possible operation of guilt is being offered in the spirit of the devil's advocate, however, since the thrust of this article has been to argue for a rising-expectations interpretation. Nevertheless, if *both* statistical comparisons are significant, the operation of guilt over the magnitude of the improvements will be included in the theoretical model.

Hypothesis 2. When the legitimate standard of fair allocation is matched by the improvement, satisfaction should be equally high regardless of the absolute level of the standard itself or the magnitude of the improvement required to match it.

This hypothesis is a direct implication of the central tenet of relative deprivation theory. The theory states that dissatisfaction with outcome depends on the existence of a discrepancy between experienced outcomes and the standard used to evaluate them rather than on the absolute outcome level itself. It follows that eliminating the discrepancy, by raising the outcomes or by lowering the standards, should also eliminate the discontent. It should also be true that if two individuals have different standards and both experience improvements that may differ in magnitude but in each case are sufficient to reduce the outcome–standard discrepancy to zero, then each should experience equal satisfaction. This hypothesis may be tested by comparing the satisfaction of subjects in the two sets of conditions where the normative standard is matched by the improvement: the low-standard–small-improvement and the high-standard–large-improvement conditions. In this

case one would predict that the statistical contrast should be *nonsignificant*, indicating no difference in satisfaction levels. This null hypothesis prediction may seem rather unusual, but in this case it is a legitimate derivation, and within the context of the other predicted significant effects, it provides a stringent test of the theory.

Hypothesis 3. The individual's satisfaction with a given level of improvement should be independently affected by the level of the allocator's resources. In general, satisfaction should be lower when the allocator's resources increase than when they remain constant or diminish.

This hypothesis suggests that subjects will use the allocator's outcomes as one standard against which to evaluate their own outcomes. Social comparison (Festinger, 1954) is a process that is central to the experience of relative deprivation. The outcomes received by others are a powerful determinant of what we decide we ourselves deserve. Crosby (1976) made it her first precondition (seeing others possess x), and numerous studies (e.g., Weick & Nesset, 1968) have demonstrated explicitly the role of social comparison as a contributor to equity judgments. Further, the literature in the area of riot participation is also consistent with the primacy of social comparison (e.g., Pettigrew, 1967; Sears & McConahay, 1973). In this paradigm, the greater the resources of the allocator, the more will be left for him/her after providing the improvement. In other words, the greater the resources, the less the improvement narrows the gap between subject's and the allocator's outcomes created by the initial inequity. This would contribute to the overall degree of inequity between the participants and should lead to increasing dissatisfaction. The predicted statistical effect is a main effect for the resource factor.

Hypothesis 4. Satisfaction with the magnitude of the improvement should be affected by the level of the allocator's resources.

This hypothesis suggests that satisfaction with the magnitude of the improvement will depend on the perceived *ability* of the allocator to provide adequate compensation and upon his/her apparent *effort* to allocate fairly. The larger the allocator's resources, the larger is the improvement that could be provided. Should only a small rather than a large increase be provided, illegitimate motives such as the allocator's greed may be suggested. This hypothesis predicts an Improvement × Resource interaction.

Finally, although it has not been specifically predicted by any of the separate hypotheses, it has been implied that all three independent variables should exert powerful effects on subjects' satisfaction with the allocations. Thus, an overall Standard × Improvement × Resources interaction might be expected to form a context within which to examine the specific predicted effects. This interaction should indicate the most marked discontent in the high-standard–small-improvement cells, especially where the allocator's resources increase. Here, the subject would experience deprivation relative to *both* standards (normative and social) simultaneously.

Method

Participants

The participants were 108 male and female undergraduates at the University of North Carolina at Chapel Hill. All participated to fulfill a course requirement. Subjects were run in groups of three, but since interaction among them was minimal and confined to a brief period before the introduction of any of the manipulations, the individual was used as the unit of analysis. Nine subjects were assigned to each of 12 experimental conditions.

Procedure

Subjects reported in groups of three for an experiment called "Organizational Behavior" and were immediately ushered into separate rooms, which were linked to the experimenter's control room via an intercom system and a set of signal lights. The experimenter explained that the focus of the experiment was on the behavior of individuals in organizations. Subjects were told that the organization they would be participating in would have three roles, worker, allocator, and government.

At this point subjects were assigned to roles by the experimenter, using a series of signal lights. All subjects discovered that they were the worker in the organization and assumed that the other two roles were being played by the other subjects. In fact, these other roles were played by the experimenter. The experimenter then visited each subject and gave him/her a "worker's folder" containing experimental materials.

The experimenter returned to the control room and resumed the instructions, which specified the duties of the worker and allocator roles. The worker was told that his/her duties would be to perform a clerical task that consisted of transcribing sets of numbers from a computer printout onto a work sheet. The number of items transcribed was to be used as a measure of worker productivity. Subjects were also told that they would be paid by the allocator over a series of eight pay periods, each of which would last 1 minute. The allocator was to receive a sum of money from the experimenter at each pay period and would then divide up that sum between himself/herself and the worker. This money was to be exchanged for tickets in a $25 lottery to be held at the end of the semester. Subjects were asked to keep a record of the allocations on the "payment record card" in their folder. The allocator was also told that later she/he would check the worker's performance.

In order to make the experimental situation more plausible and to set the stage for the introduction of the independent variables, subjects were told that the study was concerned with the degree of contact among organization members and the market conditions in which the organization was to operate. The contact aspect was used to account for the subjects being in separate rooms and to make it plausible that the allocator would be dividing up the pay without knowing how the worker was performing and would check the worker's performance only at the end of the final pay period. The "market conditions" were described simply as the amount of money made available by the experimenter to the allocator at each pay period. This explanation set up the resource manipulation in such a way as to allow the allocator's available pay to change without making him/her appear responsible for the change (in equity theory terms, to keep the allocator's "inputs" equal in all conditions, while allowing his/her outcomes to vary). At this point, the experimenter visited each subject to answer any questions about the procedure.

The experimenter then announced that the first series of pay periods was about to begin, and the subjects were instructed to begin their tasks. At 1-minute intervals, the experimenter interrupted the workers to inform them of the amount of money available to the allocator at that pay period and how the sum had been divided between them. *All* subjects were told at each of the first four pay periods that the allocator had had 24¢ available and had kept 16¢ for himself/herself and had given 8¢ to the worker. Thus, the degree of initial inequity was identical in *all* conditions.[1] At the conclusion of Pay Period 4, subjects totaled up on their payment record cards the allocations to that point.

Introduction of the Independent Variables

When everyone had finished, the experimenter continued. He indicated that the role of the government would be to mediate any possible dispute between the allocator and worker. Both were asked to fill out a "payment review request card." This would enable them to request a government review of the allocations of the first half and to express allocation desires for the second half. The government would then review these appeals and offer a fair standard for the allocations in the second half. The standard was set by a third party to make the experimental procedures more credible, especially in those cases in which the standard would not be met. This arrangement also avoided the possibility that the allocator would be perceived as having changed his/her mind about what was fair in the interval between the appeal and the second series of pay periods. It was emphasized, though, that the allocator could still allocate freely, so that the subject would perceive him/her to be *choosing* to match or not to match the standard in the second half.

When the payment review request cards had been filled out, the experimenter collected them, ostensibly delivered them to the government, and after a short interval returned them to the subjects. The experimenter returned to the control booth and said that the government had examined the appeals and had suggested that the worker should receive either 12¢ during the second half (the proximal standard) or 16¢ during the second half (the distal standard). Each of these standards was described as the "fairest way to allocate in the second half, according to a neutral third party." Subjects were asked to write down the standard at the top of their payment record cards.

The second half of the pay periods resumed at this

---

[1] This is in contrast to both the Folger (1977) and deCarufel and Schopler (1979) studies. The former confounded initial inequity with both his equity and improvement manipulations, whereas the latter confounded it with their improvement manipulation. The present study does contain a confounding of the size of the improvement with the amount received by the allocator in the various resource conditions, however (e.g., in the diminished-resource conditions: 12¢ and 6¢ vs. 16¢ and 2¢ for the worker and allocator, respectively). This type of confounding is inevitable. To remove it would have required a confound of size of improvement with either initial inequity or with allocator resources. The significance of this confounding has been discussed in the text in reference to the "gaps" between worker and allocator outcomes, especially in connection with Hypotheses 3 and 4. In the discussion of Hypothesis 1, this gap may provide an alternative to the normative-standard–outcome-discrepancy interpretation of the simple effect of the improvement within the high-standard conditions. However, it does not account for the parallel results obtained on the simple effects test of standard within the small-improvement conditions. This being the case, parsimony would dictate that the interpretation based on discrepancies from the normative standard would be the preferred one.

point. During these four pay periods, the worker received either 12¢ or 16¢ per pay period, and the amount available to the allocator to allocate on each pay period either remained the same (24¢), increased (to 36¢), or decreased to (18¢).

Dependent Variables

The main dependent variables were assessed on the "job satisfaction questionnaire," which was administered directly after the final pay period. Five measures were selected to tap various aspects of the evaluation of the improvement and were analyzed together as a multivariate set. These measures were (a) satisfaction with pay ("How satisfied were you with your pay during the second series of pay periods?"); (b) allocator fairness ("How fairly was the allocator dividing up the pay during the second series of pay periods?"); (c) satisfaction with pay change ("How satisfied were you with your second-half pay in relation to your first-half pay?"); (d) satisfaction with standard ("How satisfied were you with your second-half pay in relation to the suggestion made by the government regarding second-half allocation?"); (e) satisfaction with allocator's pay ("How satisfied were you with your second-half pay in relation to what the allocator received in the second half?"). All of these variables were measured on 9-point scales (1 = not at all, 9 = very much).

In addition, measures were taken of subjects' satisfaction with, and perceptions of fairness of, the *total* allocations, and subjects' work performance (number of items transcribed per pay period) was tallied. Finally, several additional measures were included to test the hypothesized mediation of the predicted effects. These were a magnitude estimation measure of the size of the improvement in relation to the government standard and some "intent" measures to assess subjects' perceptions of the allocator's motives.

When subjects had completed this form and an "information questionnaire," which assessed the impact of the manipulations, the experimenter brought them into a common room and fully debriefed them.

Results and Discussion

Effectiveness of the Manipulations

The allocations during the first four pay periods were designed to create in the subject the experience of having received an inequitably small share of the available pay. In fact, 99 of the 108 subjects requested a government review of these allocations, and *all* of these subjects indicated that the reason for their appeal was that they felt they had received too little pay in the first half. The 9 subjects not requesting a review were distributed across eight cells of the design. The improvement manipulation was checked with an item from the "information questionnaire," which was administered after the final pay period ("How much of a change was there in your pay from the first to the second series of pay periods?"—1 = very little, 9 = very much). The means for the small- and large-improvement conditions were 5.8 and 7.6, respectively, $F(1, 96) = 43.85$, $p < .001$. The standard manipulation was also checked with an item from the information questionnaire ("How much of a change in your pay did the government suggest?"—1 = very little, 9 = very much). The means for the low- and high-standard conditions were 6.1 and 7.9, respectively, $F(1, 96) = 48.25$, $p < .001$. Finally, the resource manipulation was checked by asking subjects to indicate how much pay had been available to the allocator during the second half. Counting 18¢, 24¢, and 36¢ as correct for the diminished, constant, and increased resource conditions, respectively, 105 of the 108 subjects (97%) responded correctly.

Overall Impact of the Independent Variables

Two measures asked subjects to consider the magnitude of the improvement in relation to the government standard. These were the magnitude estimation measure ("How did the change in pay you received from the allocator compare with the amount suggested as appropriate by the government?"—1 = too little, 9 = too much), and the satisfaction-with-standard measure from the evaluation of the improvement set of measures. Both of these showed a Standard × Improvement × Resource interaction, $F(2, 96) = 6.48$, $p < .01$, and $F(2, 96) = 5.39$, $p < .01$, respectively. Two other measures were marginally significant for this effect: how satisfied subjects were with their *total* pay, $F(2, 96) = 2.99$, $p < .06$, and the extent to which they perceived that the allocator was "trying" to allocate fairly during the second half, $F(2, 96) = 2.65$, $p < .08$. The means for these items were in accord with expectations. Satisfaction was lower and subjects felt that the improvement compared unfavorably with the standard in the high-standard–small-improvement condi-

tions, especially where the allocator's resources increased. The triple interaction was also significant on the behavioral measure of number of items transcribed during the second series of pay periods, $F(2, 96) = 4.04$, $p < .05$.[2]

Tests of the Hypotheses [3]

Hypothesis 1. This was the major "discontent" hypothesis, which predicted that subjects would be more dissatisfied with the increase in their outcome level if the improvement failed to meet the normative standard than if it did. Before proceeding to the simple effects tests, it should be noted that the overall Standard × Improvement interaction on the items in the improvement set was significant, multivariate $F(5, 92) = 5.78$, $p < .001$.

The simple effect of improvement within the high-standard conditions was significant, multivariate $F(5, 92) = 8.08$, $p < .001$. The F values for the individual improvement measures organized by test of hypothesis are presented in Table 1. The means for these items are presented in Table 2. Further evidence comes from two auxiliary measures, the extent to which subjects perceived that the allocator "went far enough" in his/her efforts to be fair and the "trying" measure discussed above. Both of these were significant for the simple effect of improvement within the high-standard conditions, $F(1, 96) = 21.34$, $p < .001$, and $F(1, 96) = 13.38$, $p < .001$, respectively. Thus when the distal standard had been legitimized, subjects felt more dissatisfied with the small improvement that failed to match it than they did with the large improvement that did. They also felt that the allocator was not trying as hard to be fair.

The simple effect of standard within the small-improvement conditions was also significant, multivariate $F(5, 92) = 6.83$, $p < .001$. The two intention measures were supportive as well: "went far enough," $F(1, 96) = 7.30$, $p < .01$, and "trying," ($p < .10$). This effect suggests that subjects were more satisfied with the small improvement when it was evaluated against the proximal rather than against the distal standard.

These data of course do not prove that the arousal, legitimation, and subsequent violation of normative standards were responsible for the Folger (1977) and deCarufel and Schopler (1979) results. They do show, however, that if the conditions they speculated about are experimentally created by separating the procedure of setting the normative standard from the actual delivery of the improvement, discontent is evident in those cases where the improvement is evaluated as inadequate. This was true whether discontent was measured using a single standard and two levels of improvement that either did or did not match it, or with a single level of improvement being evaluated against either a low or a high standard.

Recall that the guilt interpretation of deCarufel and Schopler's (1979) study was also evaluated. The simple effect of improvement within the low-standard conditions was significant, multivariate $F(5, 92) = 2.71$, $p <$

---

[2] There had been no behavioral differences during the first half when the allocators were equal across conditions. The pattern was somewhat different from that described above, but still contained strong links to the theoretical framework. The resource effect (Hypothesis 3, below) was evident, but only under the large-improvement conditions. In fact, the Improvement × Resource interaction was also significant, $F(2, 96) = 3.83$, $p < .025$. In the small-improvement conditions, productivity varied by standard. In the low-standard conditions, productivity was highest in the constant resource condition, whereas it was *lowest* in the constant resource cell under the high standard. Two things need to be said about these productivity effects. The first is that neither Folger (1977) nor deCarufel and Schopler (1979) found them in similar paradigms. Perhaps this was because in those studies, the standards of fairness were largely implicit as subjects arrived at an interpretation of the voice–improvement sequences. In the present study, the standards were explicit and allowed subjects to be aware of the unfairness throughout the second half and, thus, to alter their work output accordingly. Second, it is interesting that the hypothesized pattern of means was most clearly evident in the constant resource conditions. Here the normative standard was most clearly relevant to the subsequent allocations because there was no change in the allocator's resources to suggest the appropriateness of any other standard. This is consistent with the speculations offered above that productivity effects would be most likely under conditions of clear-cut violation or no violation of the standard.

[3] There were no effects for sex of subject, so the data for males and females were combined.

Table 1
F Values for Measures in the Improvement Set, by Hypothesis

Measure	Hypothesis 1: Simple effects tests on Standard × Improvement interaction		Hypothesis 2: Comparison of low-standard–small-improvement conditions with high-standard–large-improvement conditions			Hypothesis 3:	Hypothesis 4:
	Improvement within high standard	Standard within small improvement	Diminished resource	Constant resource	Increased resource	Resource main effect	Improvement × Resource interaction
Satisfaction with pay	6.04*	1.51	<1	<1	2.14	81.72***	1.88
Allocator fairness	3.32	1.64	1.65	<1	3.49	36.93***	6.51**
Satisfaction with pay change	6.69*	2.88	<1	1.59	5.67*	57.16***	9.08***
Satisfaction with standard	34.28***	30.18***	<1	<1	2.26	50.45***	5.36**
Satisfaction with allocator's outcome	<1	<1	<1	<1	1.09	38.57***	4.41**

* $p < .05$.
** $p < .01$.
*** $p < .001$.

.05. Inspection of the means for the items in the improvement set indicates, however, that the direction of the difference is the *opposite* of a guilt effect! Subjects evaluated the improvement *more* positively when the standard was exceeded than when it was matched. This effect, combined with the simple effect of improvement within the high-standard conditions, resulted in a significant improvement main effect, multivariate $F(5, 92) = 4.98$, $p < .001$. Clearly, there was no evidence of guilt here.

The simple effect of standard within the large-improvement conditions was *not* significant ($.10 < p < .15$) at the multivariate level, again indicating the lack of a guilt effect. The major factor in this paradigm that would seem to blunt a guilt effect is the subjects' experience of initial inequity. In studies done within the "obligation tradition" (e.g., Ger-

Table 2
Means for Measures in the Improvement Set

Measure	Low standard						High standard					
	Small improvement			Large improvement			Small improvement			Large improvement		
	Resource			Resource			Resource			Resource		
	Diminished	Constant	Increased	Diminished	Constant	Increased	Diminished	Constant	Increased	Diminished	Constant	Increased
Satisfaction with pay	8.11	8.00	2.44	8.44	7.89	4.89	7.89	6.56	2.33	8.11	8.56	3.67
Allocator fairness	7.22	7.78	2.33	6.11	6.44	5.00	6.89	6.33	2.00	6.00	8.11	4.11
Satisfaction with pay increase	8.44	8.33	3.44	8.89	7.89	6.78	8.11	7.22	2.56	8.78	7.33	5.33
Satisfaction with standard	8.56	8.78	3.89	8.00	8.00	4.56	8.00	3.00	1.78	8.00	8.56	5.22
Satisfaction with allocator's pay	6.33	7.67	1.89	5.78	7.22	4.67	7.56	6.78	1.56	6.22	6.89	3.00

Note. All of the measures in the improvement set used 9-point scales (1 = not at all, 9 = very much).

gen et al., 1975), where guilt effects are common, the subjects' need usually arises because of their bad luck or the difficulty of the task. In these cases, the aid may be viewed as *help*, which may imply the need to reciprocate at a later date. In the present situation, however, the subject is initially mistreated by the allocator. Here, the improvement is viewed as *compensation*. This interpretation of the aid by the recipient seems to have little capacity to arouse the need to repay the former tormenter (e.g., de-Carufel & Carere, Note 1).

Hypothesis 2. Hypothesis 2 examined subjects' satisfaction in those conditions where the standards were matched. Specifically, it was predicted that since in neither the low-standard–small-improvement nor in the high-standard–large-improvement condition was there a discrepancy between experienced and deserved outcomes, there should be no significant difference in satisfaction between them despite the difference in absolute outcome level. A special contrast of these conditions was run separately in each of the levels of the resource factor in anticipation of the concurrent resource main effect (Hypothesis 3, below). Thus, each contrast examined *only* the effect of matching the normative standards, holding constant the level of the allocator's resources. Consistent with the hypothesis, this contrast was *nonsignificant* at the multivariate level in each of the three resource rows ($ps > .20$). Thus, the relative deprivation hypothesis that dissatisfaction is based on a discrepancy between experienced outcomes and the standard used to evaluate them rather than on the basis of their absolute level received further support.

Hypothesis 3. Hypothesis 3 suggested that subjects would use not only the normative standards established by the government to evaluate the improvement but also the outcomes received by the allocator. It was expected that satisfaction would be lowest in those conditions where the allocator's resources increased. This prediction was confirmed. The resource main effect was significant, multivariate $F(10, 184) = 18.22$, $p < .001$. The effect was also evident on the intention items: "went far enough," $F(2, 96) = 92.79$, $p < .001$, and "trying," $F(2, 96) = 61.73$, $p < .001$, as well as satisfaction with total pay, $F(2, 96) = 39.02$, $p < .001$, and fairness of the total allocations, $F(2, 96) = 41.17$, $p < .001$. Subjects also transcribed fewer numbers onto their work sheets when the allocator's resources increased, $F(2, 96) = 3.00$, $p < .06$.

Thus, it is clear that subjects did base their perceptions of fairness and feelings of satisfaction at least in part on social comparison with the allocator's outcomes. In the increased resource conditions, the allocator was able to provide the required compensation without depriving himself/herself of a high outcome level. When the allocator continued to prosper and the gap created by the initial unfairness was not reduced, subjects felt that no real effort to be fair was being made. This dissatisfaction is reminiscent of Pettigrew's (1967) observation that blacks felt deprived relative to whites despite their economic and educational gains during the 1960s because the initial gap between blacks and whites had not been reduced and in some cases had grown wider. This perception of insufficient effort may have been reinforced in the present experiment by the fact that the increased resources were provided to the allocator by the experimenter rather than resulting from increased effort on the allocator's part.

Further evidence of the operation of social comparison processes *over and above* the effect of matching the normative standards comes from the fact that the resource main effect was significant within the low-standard–small-improvement and the high-standard–large-improvement conditions, multivariate $F(10, 184) = 7.11$, $p < .001$, and multivariate $F(10, 184) = 6.63$, $p < .001$, respectively. Thus, it seems clear that the "external" resource factor caused subjects to feel that matching *either* normative standard was an insufficient indication of the allocator's goodwill when his/her resources increased. The likely result would be a desire to renegotiate the standard, beginning anew the process of voice and (possible) improvement.

Hypothesis 4. Hypothesis 4 predicted that if the allocator were to be perceived as being

able to provide a large improvement because of increased resources, subjects would be dissatisfied if "only" a small one were granted. The predicted Improvement × Resource interaction was significant, multivariate $F(10, 184) = 3.79$, $p < .001$. The intention measures also showed the effect: "went far enough," $F(2, 96) = 2.92$, $p < .06$, and "trying," $F(2, 96) = 12.45$, $p < .001$, as did the fairness of the total allocations measure, $F(2, 96) = 4.15$, $p < .05$. It is clear that subjects took the allocator's ability to provide adequate compensation into account in their evaluation of the improvement. The small increase was seen as inadequate when the allocator's resources increased and led to lower satisfaction than did the large one.

General Discussion and Conclusions

The present study was concerned with the evaluation of the adequacy of compensation received by victims of injustice in relation to salient legitimate standards of fairness. The major theoretical perspective was that of relative deprivation. The theory was extended to predict that individuals develop expectations about what they ought to receive and that dissatisfaction may result even with *improving* outcomes if the increases do not match expectations. In fact there is evidence (Folger, 1977) that insufficient improvement may *intensify* discontent by legitimizing the victim's perceived right to higher outcomes and by bringing the former injustice into sharper relief.

Discontent with improvement was evident in two sections of the present study, in the high-standard–small-improvement conditions and in those where the allocator's pay increased. In both cases, subjects' legitimate expectations of fair allocation were violated by the allocator, apparently to his/her own benefit. In the former conditions, normative standards were legitimized by the government and not matched by the improvement; and in the latter, subjects felt spontaneously deprived relative to the allocator's own improved outcomes. This discontent was matched by perceptions of unfairness of the allocations and with the attribution that the allocator had not tried hard enough to be fair. These demonstrations are important because they serve to clarify the dynamics of the discontent in the Folger (1977) and deCarufel and Schopler (1979) studies. In those studies, the operation of normative standards was a matter of conjecture, and the role of social standards and social comparison was virtually ignored. Further, the present study found no evidence to support a guilt-based interpretation of these previous results. Thus, with the results of this experiment, the relative deprivation account of discontent with improvement in this paradigm has been considerably strengthened.

Finally, since this article opened with a discussion of discontent in "real world" settings, the focus of the discussion should be broadened briefly to show the relevance of the present research to those situations. Normative standards of allocation such as distributive justice are used in a variety of settings as a criterion of fair pay (Adams, 1965), and when they are violated, discontent may be expressed in strike action or absenteeism from the work place. Similarly, the data of Sears and McConahay (1973) indicated that Watts riot participants used normative standards such as the formal egalitarian ideology of the U.S. Constitution as a basis for their discontent with racial inequality. The normative standards used in the present study are of direct relevance to those often invoked to deal with the problems of the disadvantaged. The proximal standard is similar to statutes that prohibit injustice from that point on, whereas the distal standard represents the contention of many victims of injustice that they should receive compensation for their past misfortune. This standard finds expression in quota systems for hiring, awards of back pay lost through discrimination, and so on. Social standards are also clearly used, as Pettigrew (1967) and others have noted. As in the present study, the outcomes received by the (previous) harm-doer are often those selected by the disadvantaged as the criterion of their own deservingness.

Unlike many social psychological phenomena studied in laboratory settings, in which the task is to establish some "external validity," the literature in the area of relative

deprivation contains many striking instances of revolution, riot, and so on that have been interpreted in this framework in a post hoc fashion. What is lacking here is a sufficiently elaborated and tested *theory* that can make a priori predictions about the instigating conditions for discontent. The results of the present experiment offer cause for optimism that the rising-expectations framework under consideration here may prove fruitful in this regard.

Cardiovascular Changes During Social Competition in a Mixed-Motive Game

Lawrence F. Van Egeren
Department of Psychiatry
Michigan State University

Male and female subjects played a mixed-motive game against a male confederate under either a 20% cooperative or an 80% cooperative strategy while cardiovascular responses were computer monitored. Females had larger heart rate responses than males during play against the competitive strategy, and the opposite was true during play against the cooperative strategy. Subjects who were more competitive during the game or who scored higher on a coronary-prone (Type A) behavior scale or who reported having an action orientation toward life stress tended to have larger heart rate responses during the game than the remaining subjects. The results draw attention to the importance of covert autonomic responses for understanding overt behavioral choices in mixed-motive games and to the potential utility of this behavioral model for studying the role of psychosocial factors in psychosomatic illnesses.

Cardiovascular responses in competitive conflict situations are potentially interesting for two reasons: (a) Competitiveness (struggles for dominance, control) is a putative etiologic factor in cardiovascular disorders (Friedman & Rosenman, 1974; Henry & Ely, 1976), and (b) in human evolution, conflicts over resources were usually settled by vigorous action requiring cardiovascular arousal (Tiger & Fox, 1971); people today may carry important vestigial, now metabolically excessive, competition-released cardiovascular response tendencies. What the *form* of cardiovascular responses during mixed-motive games might be is not clear, because the nature of these games as a stressor is not clear. Cardiovascular stress studies by Obrist (e.g., Obrist et al., 1978) indicate that the type of response depends on whether stress is controllable (i.e., whether some active response is available to deal with it). When it is controllable, the heart pumps more vigorously, presumably in preparation for the action, and systolic blood pressure rises. When it is not controllable, the diastolic blood pressure rises, apparently as the result of constriction of peripheral blood vessels.

Two mixed-motive game experiments involving cardiovascular variables have been reported. In one, after an anger-induction experience, subjects played a game against a confederate of the experimenters, the anger instigator, under either predictable or unpredictable conditions (Van Egeren, Abelson, & Thornton, 1978). When the confederate's behavior was unpredictable and subjects had little control over outcomes, blood volume pulses were transmitted faster from the heart to a finger, and diastolic blood pressure decreased less during the game than when the confederate was predictable and subjects had greater control. These results seem to agree with the Obrist et al. (1978) findings for non-

I wish to thank Lawrence Sniderman and Dozier Thornton for their help in this experiment. Mr. Sniderman designed and implemented computer software for this research.

The project was supported by National Heart, Lung, and Blood Institute Grant 1 RO1 HL21319-01 to the author and by National Research Service Grant RR05656-09 awarded by the Biomedical Research Support Grant Programs, National Institute of Health, to Michigan State University.

social stressors. In another experiment, Blascovich, Nash, and Ginsburg (1978) related resting heart rates prior to a mixed-motive game to game behavior. Since the games were zero-sum, it was possible to divide the subjects into winners and losers. Male winners (i.e., the more competitive males) had faster pregame heart rates than male losers, 82 versus 74 beats per minute. Females had the opposite pattern, 82 versus 83 for winners versus losers, but this difference was nonsignificant.

Three individual differences in game response were explored in the present experiment: action orientation towards stress, a behavior pattern called Type A, and sex membership. The Type A behavior pattern, described by two cardiologists (Friedman & Rosenman, 1974), includes intense competitiveness, high achievement drive, impatience, and intense facial and vocal mannerisms. The more unhurried and relaxed person is referred to as Type B. In predictive studies, Type A's have had from two to five times the incidence of ischemic heart disease as Type B's (Rosenman, 1974; Rosenman et al., 1966). Sex differences in game behavior are often inconsistent (Davis, Laughlin, & Komorita 1976), but males seem to be more concerned with winning than females (Komorita, 1965). Because the present experiment was conducted before the appearance of the Blascovich et al. (1978) study, no prediction of an interaction between sex membership and competitiveness in heart rate was made. It was simply felt that because of male–female differences in aggression training, coded in part in sex role stereotypes surrounding aggression (Frodi, Macaulay, & Thome, 1977), social competition has a different emotional significance for men and women and that this would influence cardiovascular responses during a mixed-motive game. Specifically, it was predicted that when subjects were paired with a competitive opponent, cardiovascular arousal would be greater for males than females, greater for Type A's than Type B's, and greater for action-oriented subjects than passive-oriented subjects. The opponent for all subjects was a male confederate of the experimenter. Subjects appeared to play the game against the confederate but actually played against a laboratory computer that was programmed to be either very competitive or very cooperative. An electrocardiogram and blood volume pulses in a finger were computer monitored during the game.

Subject's Choice	Confederate's Choice: Cooperate	Confederate's Choice: Compete
Cooperate	1, 1	1, 3
Compete	3, 1	-3, -3

Figure 1. Matrix representation of payoffs. (The first number in each cell is the payoff in points to the subject. The second number is the payoff to the opponent [confederate].)

Method

Subjects

The subjects were 16 male and 16 female Michigan State University students enrolled in introductory psychology courses. Subjects of each sex were randomly assigned to treatment conditions.

Payoff Matrix

All subjects played against a first-year male medical student (confederate), using the payoff matrix shown in Figure 1.

The payoff structure was designed to make it easy to cooperate, tempting to compete, and more palatable to give in to the opposing player's competitiveness than is true in the Prisoner's Dilemma game. The major force of the game lies in the direction of a struggle for the "compete" response, but the asymmetric outcome is not as "unfair" to the loser as it is in Prisoner's Dilemma. Subjects were paid 2¢ per point.

Experimental Setting

The experiment involved the use of a computer-controlled system for the study of two-person interactions described in greater detail elsewhere (Van Egeren et al., 1978. A laboratory computer (DEC PDP 11/40 system) presented information to subjects, paced the game, collected behavioral and physiological responses, and reduced the data after each subject was run. An equipment room and a

subject room were connected by one-way mirrors and an intercom system. The subject and confederate sat side by side, 2 feet (61 cm) apart, separated by a curtain that dropped from the ceiling to the seat of the chair. The two players interacted by pressing buttons on a response panel placed in front of them. The computer "read" these button presses, decoded them, and indicated the players' moves (behaviors) on a television receiver placed so that both players could see it. Electrophysiological signals were recorded continuously from the subject and sampled intermittently at critical times by the computer (described below).

Procedure

After brief orienting instructions, electrodes and transducers were applied to the subject and the confederate. Players were handed typed instructions, taken from Rapoport and Chammah (1965) with slight modifications. A short rest was followed by a 10-trial practice (Prisoner's Dilemma) game to familiarize players with the procedures. A second brief rest was followed by new instructions and 45 plays of the game using the payoffs shown in Figure 1. The new instructions indicated that points were now worth 2¢ each. Following the game, the subject filled out two questionnaires (described below) and was debriefed and paid.

A play was initiated by display of the message "MAKE DECISION" on the TV screen, followed by a message "MAKE RESPONSE," which terminated after both subjects responded. Players responded by pressing either a green (cooperate) or red (compete) button. After the subject responded there was 3–5-sec delay before the outcome of the play was displayed for 10 sec. The display included the play number, players' choices, players' payoffs, and cumulative gains or losses. The interplay interval was random over the range of 10–20 sec.

The confederate pressed buttons during the games, but the button presses were not read by the computer. The computer followed a preprogrammed strategy to play all subjects 50% cooperative in a fixed play sequence during the practice game. The computer played 80% cooperative in a *cooperative strategy* condition and 20% cooperative in a *competitive strategy* condition during the game that followed the practice game. Eight males and eight females were assigned to each strategy condition.

Physiological Measures

Physiological responses were computer sampled every third play during the game, starting with Play Number 3. Three 6-sec samples were taken on each play sampled: (a) a prestimulus sample (PRE) prior to onset of the message "MAKE DECISION," (b) an anticipatory response sample (ANT) during the message "MAKE DECISION," and (c) an outcome sample (OUT) during display of the outcome message. Samples b and c were initiated 1 sec after onset of the messages.

1. *Electrocardiogram.* A single lead (V_5) was recorded. The output of a Grass 7P3 cardiotachometer was sampled by the computer at 10 Hz and converted to heart rate in beats per minute (bpm).

2. *Digital blood volume pulse.* Relative changes in blood volume pulse were recorded using a transmissive photoplethysmograph transducer placed on the first phalanx of the left-hand little finger. The output of a driver amplifier coupled to a Grass 7P1 preamplifier was computer sampled at 20 Hz. A computer routine for the analysis of blood volume pulses computed the trough and peak of the pulses associated with each heart beat. The term "pulse amplitude" refers to peak-minus-trough values. Mean digital pulse amplitude (DPA—mean DPA during ANT and OUT samples divided by mean DPA during PRE sample) will be reported.

3. *Respiration.* Tracings of respiratory excursions were recorded in order to detect the interference of cardiovascular activity caused by respiratory maneuvers. The tracing itself was not scored.

Questionnaires

Two questionnaires were administered at the end of the experiment: a student version of the Jenkins Activity Survey for Health Prediction (JAS) and the Habit Survey of Nervous Tension (HSNT). The JAS is a set of items sampling major components of the Type A behavior pattern (competitiveness, impatience, time urgency, etc.) developed by Jenkins (1965). In a validation study of 2,960 men, the JAS agreed with A–B classifications based on a criterion interview conducted 3 to 5 years earlier in 73% of the cases (Jenkins, Zyzanski, & Rosenman, 1974). A version of the JAS adapted for college students by Krantz, Glass, and Snyder (1974) was administered. The HSNT is a checklist of cognitive, behavioral, emotional, and autonomic responses to stressors developed by Thomas and Ross (1963). A score indicating the degree of action orientation towards stress was derived by scoring the following five items in the direction indicated: depressed feelings (−), increased activity (+), decreased activity (−), increased urge to sleep (−), and urge to be by oneself and get away from it all (−).

Results

The mean percentages of competitive responses (red button presses) of males and females playing against cooperative and competitive programmed strategies were 62% and 64% (males) and 57% and 62% (females), respectively. The percentages were computed over 45 plays of the game. An

analysis of variance of percentages of competitive responses indicated that neither main effect (sex and strategy) nor the interaction was statistically significant at a 5% alpha level.

Physiological responses during the prestimulus (PRE) period were chosen as reference points for evaluating the effects of stimuli during the anticipatory and outcome periods surrounding a behavioral choice. A two-way (Sex × Strategy) analysis of variance of PRE period heart rates, averaged over 15 trials, was computed. The sex and strategy main effects were not significant at a 5% alpha level, but the interaction was significant, $F(1, 28) = 6.01$, $p < .02$. Females playing against the competitive preprogrammed strategy had larger PRE heart rates (84 bpm) than females playing against the cooperative strategy (78 bpm); the opposite was true for males, for whom the heart rates were 70 and 81 bpm, respectively.

Two-way analyses of covariance of maximum heart rate, minimum heart rate, and heart rate range (maximum minus minimum) during the anticipatory and outcome periods were computed, with mean PRE heart rate the covariate. Measures were averaged over trials before the analysis, and tests were two-tailed. Again, the main effects were not significant, but there was a significant Sex × Strategy interaction for the maximum heart rate, $F(1, 27) = 7.50$, $p < .02$, and heart rate range, $F(1, 27) = 6.94$, $p < .02$, during the anticipatory periods, and for the minimum heart rate, $F(1, 27) = 5.43$, $p < .03$, and heart rate range, $F(1, 27) = 4.34$, $p < .05$, during the outcome period. The adjusted heart rates, displayed in Figure 2, indicate that females who played against the competitive strategy accelerated more prior to making a behavioral choice and decelerated more when the results were displayed than females who played against the cooperative strategy; the opposite was true for males. A significant Sex × Strategy interaction appeared in within-trial heart rate responses as well as between-trial heart rate levels, even when the former were adjusted for group differences in the latter.

The method for measuring blood volume pulses used in this experiment does not yield valid estimates of absolute blood volume. The prestimulus period measures were therefore not analyzed, since only relative changes from an unstimulated to a stimulated state are physiologically meaningful. Two-way analyses of variance of percentage changes in pulse amplitude from the prestimulus period to the anticipatory and outcome periods were computed. Neither the main effects nor the interaction was significant.

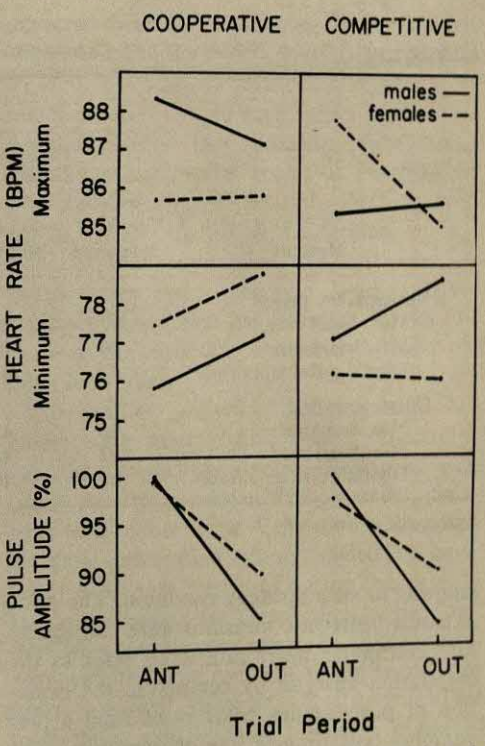

Figure 2. Comparison of cardiovascular activity of males and females during anticipatory (ANT) and outcome (OUT) periods surrounding behavioral choices while playing against either a cooperative or competitive programmed strategy. (Each data point is based on 16 subjects. The heart rates displayed have been adjusted for group differences in prestimulus heart rate level. BPM = beats per minute.)

Three behavioral measures (percentage of competitive responses, Type A behavior scores, and action-oriented coping scores) and six cardiovascular measures (maximum heart rate, minimum heart rate, and digital pulse amplitude during the anticipatory and outcome periods) were intercorrelated across

Table 1
Correlations Between Behavioral and Cardiovascular Measures

Measure	Strategy condition: Competitive			Strategy condition: Cooperative		
	% Competitive responses	Type A behavior	Action-oriented coping	% Competitive responses	Type A behavior	Action-oriented coping
Anticipatory period						
Max. heart rate	.00	−.05	−.15	.22	−.05	−.53*
Min. heart rate	.00	.07	.09	−.55*	−.07	.43*
Digital pulse amplitude	.22	.45*	.24	−.21	.16	−.04
Outcome period						
Max. heart rate	.20	.47*	.61*	.43*	−.17	−.15
Min. heart rate	.22	.45*	.59*	−.20	−.13	.53*
Digital pulse amplitude	.24	.40	−.58*	−.28	−.04	.13

* $p < .05$.

subjects in each strategy condition. The poststimulus heart rate measures were "adjusted" for prestimulus heart rate levels prior to the correlation analysis by computing the deviation of poststimulus heart rates from a prestimulus–poststimulus line of regression. The results appearing in Table 1 may be summarized as follows. First, the more the subject competed during play against the cooperative program the greater his/her heart rate acceleration when the outcomes were displayed. Second, the higher the subject's Type A questionnaire score, the larger his/her heart rate response when outcomes were displayed during play against a competitive strategy (i.e., the higher the subject's maximum and minimum heart rate following an adjustment for the subject's mean prestimulus heart rate). Third, subjects who reported having an action orientation towards stressful life events also had larger maximum and minimum heart rate responses when outcomes were displayed during play against the competitive strategy. The three behavioral measures themselves were not significantly correlated; the largest intercorrelation was .11.

Discussion

Subjects in this experiment may be classified as either "winners" or "losers" on the basis of the strategy played against them. With two exceptions, subjects who played against the cooperative strategy won the game (gained more points than the confederate), and subjects who played against the competitive strategy lost the game. Then, the unexpected finding of a Sex × Outcome interaction in heart rate agrees with the Blascovich et al. (1978) results. For both a pregame period (Blascovich et al.) and pretrial periods during the game (present experiment), winning was associated with faster pumping of blood and losing with slower pumping in males; the opposite was true for females. Furthermore, the interaction continued *within trials,* male winners having larger heart rate accelerations prior to making behavioral choices and greater slowing of the heart when the outcomes of plays were displayed than losers; and again the opposite was true for females. Males seemed to find play against the cooperative program, during which they won, more "stimulating" (eliciting a larger maximum heart rate response and a greater range of response) than play against the competitive program, during which they lost; and the opposite was true for females. How might these rather surprising results be explained?

Males and females may have approached the one-on-one competitive game differently. Males may have focused more on winning (Komorita, 1965) and females more on the chances of losing (e.g., winning may have

been more exciting to males and losing more fear provoking to females). Frodi et al. (1977) comment on sex differences in affective response to aggressive cues in their recent extensive review as follows: "Some evidence suggests that men and women react differently to external aggressive cues and provocation. . . . What may be anger-provoking for men may be anxiety-provoking for women" (p. 634).

Sex differences in dominance–subordination relations is one of the foci of the current sociobiology debate (e.g., Tiger & Fox, 1971; Wilson, 1978). Viewed this way, heart rate responses were greatest when the males were dominant (winning) and the females were subordinate (losing) in this experiment. Whether men and women are culturally or genetically conditioned to respond in such ways is one of the issues in the debate. Blascovich et al. (1978) mentioned that men and women are socialized differently for competition and have different degrees of familiarity with competitive contests. Sociobiologists point out that the hunting-gathering way of life, in which men hunted wild animals and women gathered wild plants was a human universal for more than a million years (Lee & DeVore, 1976). Surely this major adaptation over such a long period of time, with its sharp sexual division of labor, exerted different selection pressures on males and females. Thus, it is not surprising that men and women attach a different socioemotional significance to modern equivalents of the prehistoric hunt such as sporting contests (and mixed-motive games?), or so the argument goes (see Tiger & Fox, 1971).

An explanation of the results based on sex role stereotypes and conformity to social norms is also worth considering. In Western cultures males are expected to be aggressive and females to be nonaggressive. It may have been more difficult (conflictual, distressing) for the males interacting with a friendly confederate, and the females interacting with an unfriendly confederate, to perform sex role-expected behaviors than was true of their same-sex counterparts. Thus, the subjects who interacted with a confederate whose behavior was noncomplementary to their own sex role-expected behavior had larger heart rate responses than did subjects who interacted with a "complementary" confederate, regardless of sex of subject. Others have shown in modified Asch situations that pressures encouraging deviations from social norms or expectations produce physiological arousal (Back & Bogdonoff, 1963; Costell & Leiderman, 1968). Regardless of explanation, the difference between males and females in heart rate response in a competitive situation in the absence of a significant behavioral difference is quite interesting.

The nonsex individual differences in behavior were most clearly related to cardiovascular changes during the display of outcomes against a competitive opponent. Subjects with higher Type A questionnaire scores or action-orientation scores tended to have larger heart rate responses during this period. It was as though, for these subjects, the "action" was not yet over when the outcome was displayed against a competitive opponent; the heart was still preparing for action. The larger heart rate response toward a competitive opponent of subjects with high Type A questionnaire scores is in agreement with Type A behavior theory (Friedman & Rosenman, 1974), whereas the lack of correlation between the questionnaire and the actual competitiveness of subjects during the game is not. A recent experiment in our laboratory showed that subjects taken from the *extremes* of the questionnaire distribution do differ in competitiveness in a mixed-motive game (Van Egeren, 1979).

Generalization of the present results for sex is limited by the fact that both males and females played against a *male* confederate. Subjects in the Blascovich et al. (1978) experiment, however, were paired male–male and female–female and also exhibited a Sex × Outcome interaction in heart rate. It is worth noting that the difference between the female winners and losers in heart rate response was larger in the present experiment than in the Blascovich et al. experiment. Thus, the effect of females playing against an opposite-sex opponent appeared to be to accentuate the interaction in heart rate reported in both experiments.

Conclusions

First, men and women differed in cardiac response to someone else's aggressiveness, women responding more strongly to a competitive opponent and men more to a cooperative opponent. This suggests that competitive mixed-motive games have a different sociophysiological significance for men and women.

Second, cardiovascular events during mixed-motive games may help clarify motivational aspects of these games and aid in testing hypotheses about social and interpersonal contributions to heart disease.

Vocal Interruptions in Dyadic Communication as a Function of Speech and Social Anxiety

Michael Natale
Franklin and Marshall College

Elliot Entin
Ohio University

Joseph Jaffe
New York State Psychiatric Institute

Interruptions have been defined as a breach of the "turn-taking" contract in interpersonal communication. The relation between a speaker's personality and his or her propensity to interrupt was examined in 30-min unstructured conversations for 36 dyads (12 male, 12 female, and 12 mixed sex). The following predictions were made: (a) Interruptive behavior is inversely related to speech anxiety and positively related to confidence as a speaker; (b) interruptive behavior is inversely related to social anxiety (avoidance–distress; fear of negative evaluation). A stepwise multiple regression analysis was performed, controlling for the systematic effects of sex, the conversational partner's personality and amount of speech, and the speaker's use of back-channel responses. These hypotheses were confirmed for rate of total interruptions and rate of successful interruptions, for percentage of successful interruptions, and for mean duration of interruptions; the results withstood cross-validation analysis.

Ervin-Tripp (1964, 1969) and Hymes (1972) have proposed a taxonomy of the "situational determinants" of speech choice, with situational determinants being primarily defined as either endogenous or exogenous. Many studies (see Giles & Powesland, 1975, for a review) have shown speech modifications to be affected by topic, general context, formality–informality, and so forth, thus demonstrating the influence of external factors. However, the influence of internal variables, particularly personality states, on the use of certain patterns of speech has not been researched to any great extent. The few studies that have directly examined the relation of personality to conversational style have used form, as opposed to content, in constructing measures of vocal behavior. Markel, Bein, Campbell, and Shaw (1976) have shown amount of speech to be positively related to extroversion. In a series of studies, Natale (1975a, 1975b, 1976b) has demonstrated that the magnitude of engaged "matching" (modeling) for response latency, pause duration, and vocal intensity is directly related to a person's need for social approval (Social Desirability scale, Crowne & Marlowe, 1960). The general purpose of the present investigation was to further explore the relation of personality characteristics to speech behavior in an unconstrained and freewheeling conversation.

To pursue this research goal, some salient aspect of conversational behavior should be examined. Investigators have suggested that alternation of speakers is an integral part of dyadic communication that is governed by rules (Jaffe & Feldstein, 1970; Schegloff, 1968; Yngve, 1970). Empirical support of the conversational "turn-taking" mechanism has been provided by Duncan (1972, 1975), who demonstrated that behaviors in several communication modalities actively served as turn-taking signals. A relevant index of speaker

The authors would like to express appreciation to Louis Driever and Eric Bredeson for their efforts in the data collection. The also wish to thank the anonymous reviewers whose comments were extremely helpful in preparing the article.

switching is the interruption. At first glance, an interruption might be construed as always representing a battle for the conversational floor, but some evidence runs counter to that notion: (a) Stephenson, Ayling, and Rutter (1976) have reported that visual access during conversation promotes spontaneity and is associated with increased speech interruptions (Rutter & Stephenson, 1977), and (b) Gallois and Markel (1975) have provided evidence suggesting that speech interruptions may have different psychological relevance (e.g., dominance or discomfort) during different phases of a conversation. In other words, "it would be a mistake . . . to infer that each interruption event is a miniature battle for ascendancy" (Meltzer, Morris, & Hayes, 1971, p. 392). On the other hand, it may serve heuristic purposes to consider interruptions as a breach of the turn-taking process (Schegloff, 1968). If simultaneous speech is viewed as a violation of norms regulating conversational exchange, it can be expected that anxiety associated with interpersonal communication would be inversely related to an individual's propensity to interrupt. The purpose of the present study was to test this "commonsense" hypothesis in an attempt to explore the psychological factors contributing to interruption as a salient form of speech behavior.

There have been several previous studies that attemped to relate simultaneous speech to personality, but the results are not conclusive. A recent study by Feldstein, BenDebba, and Alberti (Note 1) has shown that the frequency of initiated simultaneous speech is a stable and characteristic vocal feature of an individual. Gallois and Markel (1975) published an experiment that was purported to examine the relation of social personality to conversational style. However, the only significant finding of the study was that the frequency of successful interruptions changed over the course of spontaneous conversations, and nothing was reported concerning the personality of the interrupter. We know of only two previous studies that directly assessed the relation between personality and conversational style for simultaneous speech. Feldstein, Alberti, BenDebba, and Welkowitz (Note 2) used Cattell's Sixteen Personality Factor Questionnaire (16PF) to measure dimensions of personality and found that "persons who are relaxed, complacent, secure, and not positively dependent on the approval of others tend to initiate more simultaneous speech than those who are generally apprehensive, self-reproaching, tense, and frustrated." A recent study by Ferguson (1977) examined the relation of dominance to the propensity to interrupt and found that interruptive speech was not affected by the dominance measure. The results of Feldstein et al.'s study (Note 2) are inconclusive for two reasons: (a) The personality descriptions were based on factor scores from the 16PF, yet it has been emphasized by Bourchard and Porer (cited in Buros, 1972, p. 329) that because of weak predictive validity, personality assessment from Cattell's scales or profile interpretation is not desirable; (b) the results of Feldstein et al. were obtained from an uncross-validated regression analysis of only 24 subjects, thus obscuring the generalizability of the findings.

To sum up, Feldstein et al.'s (Note 2) data do suggest that tense and apprehensive people are less likely to initiate simultaneous speech. This tentative finding is consonant with the hypothesis of the present study: The more fear individuals have concerning their speaking role, (i.e., speech anxiety), the less likely it is that they will interrupt. This notion was tested in unconstrained conversations of previously unacquainted individuals so that "task" factors were minimized. We also "covaried out" the effects of potential moderator variables (speaking style and personality of dyadic partner) so that the relation of an individual's personality to interruption behavior could be distinctly assessed.

Method

Subjects

The subjects were 72 students (ages 18 to 20) of Ohio University enrolled in introductory psychology courses who volunteered and who received course credit for their participation. The subjects were randomly paired: 12 male dyads, 12 female dyads, and 12 mixed-sex dyads. It was also a necessary condition that the dyadic partners not be previously

acquainted with each other and that English be their native language.

Personality Measures

Self-reports of speech anxiety. Four self-report measures were selected to assess anxiety during conversation and the generalization of anxiety to other social situations.

1. An overall self-report rating of General Speech Anxiety on a scale from 1 (no anxiety) to 9 (extreme anxiety). This simple measure has been successfully used by Fremouw and Harmatz (1975), and because of its face validity we deemed it appropriate.

2. The Personal Report of Confidence as a Speaker (Paul, 1966) requires the subject to complete 30 true–false items that assess the respondent's feelings, thoughts, and behavior during the most recent speech. This scale has been shown to be both reliable and valid (Paul, 1966, p. 48).

3. The Social Avoidance and Distress scale consists of 28 items that assess an individual's generalized anxiety in many interpersonal situations. Watson and Friend (1969) demonstrated this scale to have average reliability ($r = .85$) and to predict social-avoidance behavior.

4. The Fear of Negative Evaluation scale (30 items) measures the magnitude of a subject's concern about other people's evaluations of him. Watson and Friend (1969) showed this scale to have acceptable reliability ($r = .72$) and to predict social-avoidance behavior.

All four of these measures can be used to assess speech anxiety (Fremouw & Harmatz, 1975); however, it should be noted that the speaker anxiety and confidence measures, Scales 1 and 2, evaluate anxiety directly associated with the *speech act,* whereas Scales 3 and 4 assess general anxiety associated with the *communication situation.*

Social desirability. A measure of the need for approval was obtained by using the Marlowe–Crowne scale (Crowne & Marlowe, 1960). Although not directly related to the main hypothesis of the present study, this scale was administered because prior research (Natale, 1976b) suggested that an individual's need for social desirability was related to his propensity to interrupt.

Definition of Speech Interruption Behavior

For the purposes of the present study, an interruption was defined as the occurrence of simultaneous speech and was assigned to the participant who initiated speech while not possessing the "conversational floor." It should be noted that for any one individual, possession of the conversational floor begins with the first sound that person utters alone and ends with the first unilateral sound uttered by the other participant. This definition of speech interruption has been used by other investigators (Jaffe & Feldstein, 1970; Meltzer et al., 1971).

Jaffe and Feldstein (1970) summarized a decade of interview research that clearly demonstrated the ability of an analogue-to-digital computer (Automatic Vocal Transacter Analyzer—AVTA) to measure the noise and silence pattern of recorded dialogue. Using AVTA, speech was measured at 300-msec intervals, and a separate analysis of speech parameters was provided for each subject in a dyad. The interested reader is referred to Jaffe (1970) for a sophisticated discussion of the methodology and validity of speech measures derived from the AVTA system. There is, however, an issue of measurement that deserves note. There is a possibility that brief utterances, such as "yes" or "uh huh," which the listener intersperses during the speaker's pauses and speech may be classified by the computer (AVTA) as interruptions.[1] These brief utterances (back-channel responses) are easily recognized and have been shown to function as the opposite of a speaker-switching device, in that they appear to ensure that the speaker who is holding the conversational floor continues to do so (Duncan, 1975). These vocal back-channel signals are not attempts to change the conversational floor and therefore should not be included in the analysis of interruptions (Meltzer et al., 1971, p. 395).[2] To this end, back-channel responses were scored by a trained rater. Each recorded dialogue was heard twice by this judge so that each conversationalist's back-channel responses were scored separately. Concerning the reliability of the trained judge's scoring of back-channel responses, a pilot showed the rater to have a 91% agreement with one of the experimenters (MN). It should be noted that back-channel responses were the only speech measure not obtained from AVTA.

Total speech interruptions. An interruption was defined as the occurrence of simultaneous speech and was assigned to the participant who initiated speech while not possessing the conversational floor. Possession of the conversational floor begins with the first sound a subject utters alone and ends with the first unilateral sound uttered by the conversational partner. As a measure, *total speech interruptions* does not discriminate between interruptions that result in a change of the conversational floor and those in which the interrupted speaker retains possession of conversational floor.

Successful speech interruptions. A speech interruption that results in a speaker switch is a successful interruption. This measure is assigned to the speaker who did not originally possess the conversational floor.

Percentage of successful interruptions. It should be noted that unsuccessful and successful interruptions summate to total speech interruptions. The

---

[1] The vocalizations have been variously called "listener responses" (Dittman & Llewellyn, 1967), "attention signal" (Kendon, 1967), and backchannel responses (Duncan, 1975; Yngve, 1970). In this article we employ the latter term.

[2] The authors thank Robert Krauss, Department of Psychology, Columbia University, for clarifying this issue.

proportion of total interruptions that were successful (i.e., that resulted in a speaker switch) was calculated.

Mean duration of interruption. Jaffe and Feldstein's (1970) AVTA allows for the calculation of duration of interruption in .1-sec units. The mean duration was calculated on each subject's total speech interruptions.

Total speech time. The total vocalization time of each conversationalist was calculated, via AVTA, using 300-msec recording intervals.

Apparatus

The conversation between the pair of subjects took place in one of two conditions: (a) with the conversationalists in the same room (10×18 ft., or 3×5 m), sitting 15 ft. apart in half-view of each other (from the waist up); (b) with the subjects in separate rooms but in half-view of each other, sitting 2 ft. from a full window and directly facing each other. Approximately half of the conversations were recorded in each condition.[3]

All subjects wore a headset consisting of a Kellogg earset and a Sony omnidirectional microphone that rested approximately 1 in. from the mouth of the subject. The close proximity of the microphone allowed us to maintain a low gain on the recorder, the result of this procedure being that each conversationalist's speech was clearly recorded without spillover from his dyadic partner. The conversationalists heard each other monophonically via the earset. The recordings were made on a Sony stereo tape recorder that was out of view of the subjects.

As stated, Jaffe and Feldstein's (1970) AVTA system was used to obtain all the speech measures with the exception of back-channel responses, which were scored by an independent rater. AVTA is an analogue-to-digital computer that accepts stereo recordings of a dialogue and provides the previously described speech parameters for each conversationalist.

Procedure

Prior to the conversational task, a pair of subjects was asked to fill out the personality measures described earlier (25 to 40 min); then some preliminary instructions were given to ensure proper tape-recording. The subjects were told that this was merely an experiment on interpersonal communication and that the only experimental task was to talk freely with their partner. At this point, the research assistant activated the tape recorder and left the room. Each recorded dialogue lasted exactly 30 min, whereupon the research assistant returned to the room, terminated the conversation, and explained the purpose of the study to the participants.

Statistical Analysis

The 36 dyads were randomly divided into two equal-sized samples, with the stipulation that each sample have an equal number of male, female, and mixed-sex dyads. One was called the initial sample and the other the cross-validated sample. All analyses were first conducted on the initial sample of 18 dyads.[4] In case the regression analysis (described later) capitalized upon chance, the results were validated using the cross-validated sample.

Stepwise regression. For the initial sample, a stepwise regression analysis was used to evaluate the contribution of an individual's self-reported speech anxiety and desire for social approval (predictors) to the use of the following interruption behaviors (dependent variables): total speech interruptions, successful speech interruptions, and mean duration of speech interruptions. A separate regression analysis was performed for each dependent variable.

Since the purpose of the present study was to determine the precise effect of specific personality measures on an individual's propensity to interrupt, it was necessary to eliminate the effects of the following modifying variables in the regression analysis for the initial sample. (a) It is obvious that an individual will have greater opportunity to interrupt a talkative partner and less opportunity to interrupt a taciturn partner; therefore, the effect of the partner's total speech time should be eliminated in evaluating the relation of an individual's personality to his or her propensity to interrupt. (b) As previously mentioned, certain brief interruptions (back-channel responses) are not intended by the speaker to indicate a desire to grab the conversational floor; hence, any study wishing to examine interruptions as a speaker-switching mechanism should eliminate the role of back-channel responses (Melzer et al., 1971, p. 395). (c) A *person perception* variable may also influence an individual's behavior in the interpersonal situation; therefore, the personality traits of the dyadic partner should be taken into account when assessing the individual's behavior. (d) It has been suggested that the individual's sex and the dyad's sex affect the use of interruptions (Zimmerman & West, 1975); hence, these sex variables must be taken into account.

In this light, the stepwise regression of an individual's personality measures to his or her interruptive behavior was performed using the individual's back-channel responses, the speaking time and personality measures of the conversational partner, and the individual's and the dyad's (male, female, mixed) sex as covariates.

Marsden, Kalter, and Ericson (1974) have pointed out that this analysis can easily be achieved by forc-

---

[3] The statistical technique used in this study was stepwise multiple regression. This regression procedure capitalizes on the particular characteristics of the sample; therefore, a slight variation in the recording procedures was viewed by the experimenters to provide robustness to the findings.

[4] There were 18 dyads in the initial sample, but each dyad member was treated as a subject in the analysis. Hence, $N = 36$ for the initial sample.

ing the order of the predictors. Stepwise multiple regression works by adding one variable at a time to the regression while assessing to determine whether the independent variables significantly increase the prediction of the dependent variable. If one wants to treat certain predictors as covariates, all that is necessary is to force the entry of these covariates into the multiple regression prior to the other free-floating predictors (see Cohen & Cohen, 1975, for a detailed discussion of this technique). In other words, there were two sets of independent variables used in the stepwise regression procedure: a set of covariates followed by a set of predictors of theoretical value (variates). The order of the independent variables within each set of predictors was "free," that is, selected by the computer to maximize prediction of the dependent variable. This straightforward procedure was used in the present study. To restate, the multiple regression analysis tested the relation between an individual's personality and speech-interruption behavior, while controlling for the systematic effects of sex, of the conversational partner's personality and amount of speech, and of the speaker's use of back-channel responses.

Cross-validation technique. As stated earlier, a stepwise regression was used in the initial sample. This statistical procedure adds (steps) one variable at a time to the regression for the purpose of increasing the prediction of the criterion. When the computer is free to determine the order of the predictors, it is possible that the stepwise procedure will capitalize on chance relationships. In the present study, the predictors were grouped as two sets (covariates and variates), and the computer freely determined their order *within the set.* Thus a cross-validation was not absolutely necessary but was performed for the purpose of testing the replicability of the findings.

The regression formula (beta weights) from the first sample was imposed on the independent variables of the second, cross-validation, sample. This procedure produces *predicted* values of the dependent variable in the cross-validated sample. For the second sample, a zero-order correlation between the estimated and the actual dependent variables was performed at each step of the regression and was considered the cross-validated multiple regression coefficient.

Results

Table 1 presents the initial stepwise correlations obtained for Sample 1. A separate regression analysis was performed for each dependent variable. The set of covariates was entered as predictors prior to the set of variates, but within each set the computer was free to order the predictor so as to maximize prediction. The regression of each independent variable to the dependent variable was tested for statistical significance by an F ratio (Cohen & Cohen, 1975, p. 107) that took into account the effect of other independent variables. In other words, the F test indicated whether the increment in variance accounted for was significant when a predictor was added.

The multiple correlations obtained in Sample 1 (Table 1) were cross-validated in a second sample. The cross-validation procedure (see Method) used all of the predictors (covariates and variates), but for the sake of brevity, the cross-validated coefficients are reported (see Table 2) only for the significant predictors of the first sample.

Total Interruptions

In reference to the total amount of interruptions initiated by a speaker in the dyadic situation, the total speaking time of the conversational partner was a strong positive factor ($r = .79$, 63% of the variance). Obvious logic explains this finding—the more a person talks, the more likely it is that he or she will be interrupted. Examination of Table 1 also shows another covariate to have had an effect on a speaker's use of interruptions. It was found that males interrupted more often than females (correlation increased from .79 to .83; additional variance accounted for was 7%), a finding that Zimmerman and West (1975) have also reported. There was no significant contribution of the conversational partner's personality traits to the speaker's propensity to interrupt. Of direct relevance to the hypothesis of the present study, examination of the variates in Table 1 shows the speaker's desire for social approval to be positively related to the total use of interruptions.

Examination of Table 2 shows that even after a cross-validation procedure a person's desire for social approval was still shown to be significantly related to his or her use of interruptions. The relationship of partner's speaking time and sex to rate of vocal interruptions also withstood cross-validation (see Table 2).

Successful Interruptions

This dependent measure is an expression of interruptions that result in the interrupter gaining the conversational floor. In this sense,

Note. Sample 1, $n = 36$. A separate multiple regression analysis was performed for each dependent variable (criterion). The ability of each independent variable to make a unique nonzero contribution to R^2 was tested by examining the semipartial correlation (sr) of each predictor to the criteria as follows:

$$= \frac{sr^2/1}{(1 - R^2)/N - k - 1}$$

where N = number of subjects (36) and k = number of independent variables; $df = 1\ (N - k - 1)$ (Cohen & Cohen, 1975, p. 107).

[a] P denotes partner and S denotes speaker.

[b] + or − indicates the direction of the relationship of each predictor to the dependent variable.

* $p < .05$.
** $p < .025$.
*** $p < .01$.
**** $p < .001$.

a multiple regression with this dependent measure provides a more stringent test of the hypothesized relations between personality and interruptive behavior. Looking at Table 1, one sees that a person's use of back-channel responses was significantly related to his or her overall rate of successful interruptions ($r = .46$, 21% of the variance). It was also the case that the conversational partner's amount of speech was positively related to a speaker's use of successful interruptions (multiple R increased from .47 to .52). The personality characteristics of the conversational partner were not significantly related to the magnitude of successful interruptions used by a speaker.

Over and above the effects of covariates on the incidence of successful interruptions, the hypothesized effect of the speaker's personality was demonstrated. Table 1 shows a speaker's general speech anxiety to be inversely related to his or her rate of successful

interruptions; the increase in the accounted for variance was rather large (18%). Table 2 shows this finding to be generalizable under cross-validation procedures. The positive relation of a speaker's back-channel responses to the frequency of successful interruptions used by the same speaker was marginally significant under cross-validation procedures ($r = .29, p < .07$).

Percentage of Successful Interruptions

This measure reflects the proportion of initiated interruptions that result in a speaker switch in favor of the interrupter. Table 1 shows that a speaker's percentage of successful interruptions was positively related to his or her conversational partner's confidence as a speaker ($r = .43$, 18.7% of the variance). The speaker's general anxiety about social situations (avoidance–distress) was negatively related to his or her propensity to effect a speaker switch once he or she initiated an interruption. In other words, a person who has high social anxiety is less likely to persist in his or her interruptions. It should be noted that the speaker's social avoidance–distress accounted for a substantial amount of the variance over and above the effects of the covariates (8.75%, see Table 1). This relation of percentage of successful interruptions to speaker's avoidance–distress was also cross-validated (see Table 2).

Mean Duration of Interruption

This measure can be conceptualized as an index of a person's tenacity in effecting a speaker switch. In other words, when an individual initiates an interruption does that individual prolong or shorten the simultaneous speech situation and how does this relate to his or her personality? Before answering this question, we look at the effect of the covariates on this dependent measure. Table 1 shows the conversational partner's amount of speech to be positively related to how long an individual persists in an interruption ($r = .64$, 41% of variance, Table 1). There was a nonsignificant trend ($p \leq .08$) for males to engage in longer interruptions (Table 1). This effect of sex on interruptive behavior agrees with the findings of Zimmerman and West (1975).

Table 2
Cross-Validated Multiple Regression Correlations Between Speech Interruptions and Personality

Dependent variable	Multiple regression coefficient[a]
Total interruptions	
P's speech time	.35*
S's sex	.41**
S's need for social approval	.44**
Successful interruptions	
S's back channel	.29
S's speech anxiety	.36*
Percentage of successful interruptions	
P's confidence	.21
S's avoidance–distress	.38*
Mean duration of interruption	
P's speech time	.39*
S's avoidance–distress	.45**

Note. Sample 2, $n = 36$. The product-moment correlation between the predicted and the observed dependent variable at each step of the regression was defined as the cross-validated regression coefficient ($df = 34$, two-tailed test). Only those covariates and variates that showed significant predictive power in the initial regression (see Table 1) were used in the above analysis.

[a] P denotes partner and S denotes speaker.

* $p < .05$.

** $p < .01$.

The hypothesized effect of personality on interruption was again supported by the regression analysis. Looking at the variates in Table 1, we see that an individual's general social anxiety (avoidance–distress) was negatively related to the mean duration of the interruptions he or she initiated. The predicted variance contributed by this variable was 13.2%.

Total Speech Time

The relation of personality to speaking time was not directly relevant to the hypothesis of the present study. However, a multiple regression analysis was performed for the sake of completeness, since the information was available. Table 3 shows that the sex and the personality characteristics of the conversa-

** $p < .01$.

tional partner were poorly related to the total amount of speech time of a speaker. Looking at the variates in Table 3 it is apparent that the subjects' speech anxiety was inversely related to their speech time.

Back-Channel Responses

Although research has suggested that certain brief interjections are "listener responses" (Duncan, 1975), their relation to the personality characteristics of the listener or the speaker has not been examined. Data from the present study allowed us to address this question. Table 3 shows a person's use of back-channel interruptions to be related uniquely to the personality of the individual who is emitting the listener response. The conversational partner's personality was not significantly related to the use of back-channel responses by an individual (see Table 3). A speaker's use of back-channel responses was found to be positively related to his or her fear of negative evaluation; 14% of the variance was accounted for by this variable (Table 3). Table 4 shows this finding to withstand cross-validation.

Discussion

Specific Findings

In evaluating the meaningfulness of the results, two questions should be kept in mind. (a) When a predictor shows a significant relation to the dependent variable, what is the amount of variance accounted for? In other words, even if the addition of a variable to the multiple regression increases R^2 significantly, the increase may be quite small. (b) Does the significance of the predictors sustain cross-validation procedures? With these points in mind, a discussion follows.

Concerning the total rate of vocal interruption that a person displays (see Table 1), the amount of speaking time of a conversational partner is a strong determinant. The more people talk, the greater their chance of being interrupted. This very basic finding indicates the limits of a psychological explanation of speech interruptions. In other words, the present study shows that roughly two thirds of all vocal interruptions can be explained in terms of physical opportunity as opposed to personality factors. Within this limit, a significant but small proportion of total interruptions was predicted by the sex of the speaker; males interrupted more often than females. This effect of sex on interruptive behavior verifies the earlier findings of Zimmerman and West (1975), which showed males to interrupt more often than females.

Personality characteristics of the conversational partner did not significantly contribute to the total use of interruptions. This finding, together with the positive relation of a speaker's desire for social approval to vocal interruption behavior (see Table 1), may indicate the inappropriateness of conceptualiz-

Table 4
Cross-Validated Multiple Correlations Between Total Speech Time Back-Channel Responses and Personality

Dependent variable	Multiple regression coefficient[a]
Total speech time	
P's avoidance–distress	.38*
S's speech anxiety	.43**
Back-channel responses	
S's negative evaluation	.51**

Note. $n = 36$. The product-moment correlation between the predicted and the observed dependent variable at each step of the regression was defined as the cross-validated regression coefficient ($df = 35$, two-tailed test). Only those covariates and variates that showed significant predictive power in the initial regression (see Table 3) were used in the above analysis.

[a] P denotes partner and S denotes speaker.

* $p < .05$.

** $p < .01$.

ing speech interruptions as invariably representing a contest for the conversational floor. In the introduction we noted that speech interruptions correlate positively with intimacy (e.g., Rutter & Stephenson, 1977). This interpretation of speech interruptions may explain why a person who has a high need for social approval tends to interrupt more often. Interruptions, rather than representing a violation of speaker-switching roles, may serve to express joint enthusiasm and the need for an individual to achieve this level of communication (a measure of social desirability).

However, simultaneous speech may represent conversational floor grabbing in the situations where successful interruptions were examined. Support for this notion comes from the multiple regression analysis (Table 1) that used successful interruptions as the dependent variable: An individual's speech anxiety had a sizable negative relation to the number of successful interruptions. In this light, partial support for the original hypothesis can be stated as follows: Vocal interruptions represent an "offense" against the turn-taking rules and as such are negatively related to an individual's speech anxiety, but only in the case of successful interruptions. This finding adds validity to the notion that certain brief interjections (i.e., back-channel responses) are emitted for the sole purpose of reinforcing the listening role. The data in Tables 3 and 4 show fear of negative evaluation to be significantly related to the use of back-channel responses. Specifically, a person's fear of negative evaluation was positively related to his or her propensity to utter brief interruptions (i.e., back-channel responses). The positive social function of back-channel responses is apparently strong enough to answer to a person's need to be positively evaluated. The positive relationship between a person's back-channel responses and his or her use of successful interruptions is not readily interpretable, thus indicating the need of future research to clarify the psychological role of back-channel responses.

The percentage of successful interruptions can be taken as a measure of a person's intensity in forcing his or her way into a conversation. After initiating an interruption, does an individual continue until he or she takes over the conversational floor? Interestingly, the percentage measure of interruptions yielded a solid relation to the partner's personality (see Table 1). The more confident the partner felt about speaking, the higher the proportion of successful interruptions by the other subject (approximately 18% of the predicted variance was accounted for by the partner's speech confidence). One possible interpretation of this finding is that the partner communicates a positive attitude toward interpersonal communication and thus somehow gives an interrupter more confidence to attempt speaker switches. Conversely, if we perceive a person to be highly sensitive about conversing, we might avoid trying tenaciously to grab the conversational floor. Future research will have to clarify the role of person perception variables in the use of simultaneous speech.

The intensity measure (percentage successful) of interruptions was strongly related to a speaker's social anxiety. The more anxiety (avoidance–distress) a person has concerning social interaction, the smaller his or her proportion of successful interruptions. This finding offers direct support of the general hypothesis of the present study: The use of speech interruptions was negatively related to interpersonal anxiety.

The strong relation between partners' speaking time and interruption duration (see Table 1) is self-explanatory. The duration of the interruption was negatively related to social anxiety (avoidance–distress), thus replicating a similar relation between social anxiety and the percentage of successful interruptions. The findings presented in Tables 1 and 2 can be summed up as follows:

1. A significant negative relation between interruption and a speaker's interpersonal anxiety was demonstrated for all interruption measures with the exception of total interruptions. This finding indicates that analysis of speech interruptions necessitates the delineation of the types of simultaneous speech.

2. The fact that a person's desire for social approval had a modest but significant positive relation to interruptive behavior indicates that speech interruptions may not always

represent contests for the conversational floor. An interruption can also express a positive state of excitement and the like.

3. The findings that males engaged in vocal interruption more than females did fully supports the earlier research of Zimmerman and West (1975).

4. The present findings indicate that the partner's speech time was strongly related to a subject's interruptive rate. The more people talk, the more likely they will be interrupted.

It was also found (Tables 3 and 4) that a person's speech anxiety was negatively related to total speaking time. To the extent that speech anxiety determines speaking time of an individual, it also affects the interruption rate of the conversational partner. The personalities of the dyadic partners interact and influence each other's behavior, but it was the speaker's, as opposed to the partner's, personality that was the strongest predictor of vocal interruptions.

General Theoretical Relevance

Of general theoretical interest is the relation between verbal behavior and personality. Clinical psychology has traditionally emphasized the relation of verbal content to the presence of psychopathology (e.g., thought disorder, delusions, schizophrenia, subjective unhappiness, depression). Over the past decade, researchers have tried to develop objective scoring systems for verbal behavior in an attempt to overcome some of the problems of unreliability (e.g., spectral analysis of voice for anxiety, Smith, 1974; interaction chronography, Jaffe & Feldstein, 1970, and Matarazzo & Weins, 1972). Although automation of vocal measures has vastly improved reliability, the relation of these speech measures to variables of psychological interest has not been shown to be strong. This may be due to the fact that formal aspects of speech may represent an endogenous (neurolinguistic) characteristic of communication that is to a great degree invariant. Evidence for this notion comes from Jaffe and Feldstein (1970), who have shown that speech timing of monologues and dialogues can be accounted for by a Markovian (stochastic) process.[5]

If speech timing of dyadic interaction is partially predicted by a "random walk" model then it follows that psychological factors might only partially affect conversational timing. This may account for the fact that only a minor, albeit significant, proportion of speech interruptions was affected by the personality measures used in the present study. The stochastic nature of dialogic speech timing may also account for Ferguson's (1977) meager empirical support of the long-held clinical notion that interruptions represent dominance in family interactions.

However, there is some evidence that suggests that the Markovian nature of dialogic speech timing (Jaffe & Feldstein, 1970) breaks down in the course of a conversation. Cobb (1973) showed that there were long-term periodicities in the speech timing of individuals who knew each other. The presence of speech rhythms obviously violates a fundamental assumption of Jaffe and Feldstein's stochastic model; the transitional probabilities of the vocal parameters cannot be assumed to be constant. It appears that the timing of speech, and therefore interruptions, roughly obeys stochastic principles which are nonetheless modified by external variables (personality, task orientations, etc.). This was also found to be the case for gaze behavior. Natale (1976a) found the timing of gaze behaviors generally to obey Markovian principles, but it was also observed that prolonged looks could not be accounted for by the stochastic model.

In summary, it appears that although the timing of gaze and of speech (including speech interruptions) generally obeys Markovian principles, these behaviors still are susceptible to influence. The present study examined only speech interruption behavior in free conversations. It may be that a variety of situational variables are more likely to elicit vocal interruptions of a psychological nature. Feldstein and Welkowitz (1978, p. 341) have

[5] Gaze timing, often hypothesized to reflect cognitive (Rutter & Stephenson, 1977) and affective state (Natale, 1977), has also been shown to obey stochastic principles (Natale, 1976a; Rutter, Stephenson, Lazzerini, Ayling, & White, 1977).

stated that an AVTA (Jaffe & Feldstein, 1970) analysis of free conversations shows speech interruptions (successful and nonsuccessful) generally to have durations of approximately .4 sec. (The present study obtained the same finding.) Feldstein and Welkowitz have aptly noted that Meltzer et al. (1971) reported instances of simultaneous speech as long as 6 sec and suggest that the difference in findings may be a function of task. Meltzer et al. recorded speech interruptions during problem-solving sessions, whereas Feldstein and Welkowitz (1978) and the present study examined naturalistic conversations. The relevant point is that casual social conversation and task-oriented dialogue may elicit different patterns of speech interruption reflecting different relation to personality. It may be that interpersonal anxiety accounts for a larger proportion of interruption in interviews, therapy, and the like. Future research must examine these questions.

Another theoretical issue relevant to the present findings is the extent to which the outcome of simultaneous speech is determined by cognitive variables. Morris (1971) and Meltzer et al. (1971) have provided sound evidence for the role of vocal amplitude in determining interruption outcome. These investigators have suggested that the briefness of simultaneous speech indicates the small role of semantic content and hence the importance of physicalistic cues (vocal amplitude) in interruption outcome. But Feldstein and Welkowitz have stated that "amplitude may function as a mediating factor that allows speakers to respond quickly to content, or it may be so highly related to content . . . that its role in determining outcome is artifactual" (1978, p. 353). The relation of interruption outcome to cognitive processes is not ruled out and does indeed receive indirect support from the present study. Successful interruptions were negatively related to speech anxiety and social anxiety, but the accounted for variance was moderate. Also, duration of interruption, which averaged a mere .45 sec, was significantly related to personality. The fact that interruption behavior is subject to individual differences (Notes 1 and 2), and is related in some degree to personality, does suggest that the role of cognitive processes in determining interruption behavior cannot be ruled out.

Finally, the issue of whether an interruption represents a fight for the conversational floor was not directly examined in the present study. It will be recalled that for the sake of examining the relation of simultaneous speech to personality, we assumed that vocal interruptions represent a contest for speaking. However, there is evidence that suggests that interruptions represent spontaneity and positive states (Stephenson et al., 1976). This positive relation between interpersonal communication and interruptions could account for the moderate negative relation between interpersonal anxiety and the initiation of simultaneous speech. It could be that vocal interruptions are either positive (emotional) or negative (competitive) according to situational determinants. Future research should examine the relation of cognitive, mood, task, and personality variables to formal aspects of dialogue so that the magic of "good" and "bad" conversations might be discovered.

Multidimensional Input in Equity Theory

Arthur J. Farkas and Norman H. Anderson
University of California, San Diego

Multiple dimensions of input, which are typical of equity judgments in practical situations, may be handled in two ways. The standard assumption of *input integration* implies that the input cues are summed for each individual to yield a single unitary value of input for each separate person; the ratio model of equity division then applies to these unitary input values. Input integration thus transforms the multidimensional stimulus field into a one-dimensional value of input that mediates the equity division. The alternative assumption of *equity integration* implies a reverse order of processing: First, the ratio model is applied to make an implicit equity division along each separate input dimension; the resulting equity ratios are then averaged to yield a final judgment. The difference in processing order implies different patterns of interaction that thus serve to test the two assumptions. The results of the present research agreed very well with the hypothesized rule of equity integration when the input dimensions were dissimilar. When the input dimensions were similar, the results agreed moderately well with the hypothesized rule of input integration, although there were small, worrisome discrepancies. Overall, the results provide some promising support for a cognitive algebra of equity.

It is widely assumed that equity should obtain when a person's *outcome* is proportional to *input*. But how can this simple rule apply when input is multidimensional? In many social situations a person's deservingness depends not only on concrete accomplishment but also on how hard the person tried. How can a one-dimensional outcome be proportional to a two-dimensional input? How can proportionality be maintained when the person tried hard but accomplished very little? Or accomplished a great deal with little effort?

This problem of multidimensional input is fundamental in equity theory. Adams (1965) has emphasized how numerous factors (seniority, age, educational and family background, for example) can all affect the perceived value of input. Similarly, a person might consider his or her intentions, efforts, or even need, as part of input, over and above actual performance. In social practice, therefore, input will generally be multidimensional. Any theory of equity must solve the problem of multidimensional input.

An obvious solution is to assume a one-dimensional mediator. All relevant stimulus information about the person would be integrated to obtain a single value of deservingness. The person's outcome would then be taken as proportional to this deservingness value. Under this hypothesis of *input integration*, the multidimensionality resides in the stimulus field but the effective mediator is itself one-dimensional.

This hypothesis of input integration has been taken more or less for granted. Adams (1965) and Walster, Berscheid, and Walster (1976) have assumed an input summation rule, while Anderson (1976a) and Leventhal (1976) have suggested an averaging rule.

This work was supported by National Science Foundation Grants GS-36918 and BNS 75-21235. Support was also received from grants from the National Institute of Mental Health to the Center for Human Information Processing, University of California, San Diego. Parts of Experiment 1 were presented at the Western Psychological Association meetings, San Francisco, April 1974.

Only one experiment (Anderson, 1976a) has provided an experimental test, however, and these results raised doubt about the validity of any rule of input integration.

The assumption of input integration is stringent. It requires that all the diverse determinants of input be reduced to a common currency. That might be hard to do with qualitatively distinct dimensions, such as actual accomplishment and effort, for example, or productivity and seniority. To integrate such different dimensions into a unitary, one-dimensional mediator may be difficult.

There may be an easier way to handle multidimensional input. The first step would be an implicit equity division for each separate dimension of input. That involves comparing the several persons on only one dimension at a time. Further, these implicit divisions are themselves comparable across different dimensions, because they all represent relative deservingness values. Hence, they should be easily integrated to obtain an overall division.

This scheme may be called *equity integration* (Anderson, 1976a), because it is the implicit equity divisions that are integrated. Both steps in equity integration involve quantities that are naturally comparable. Thus, equity integration offers a psychologically attractive way to handle multidimensional input.

The present experiment was designed to test between the two hypotheses of input integration and equity integration. This turns out to be fairly straightforward by means of cognitive algebra. However, it requires an explicit statement of the two hypotheses. For simplicity, this statement will be restricted to the equity model employed in information integration theory (Anderson, 1976a; Anderson & Farkas, 1975; Farkas, 1977; Farkas & Anderson, Note 1; Anderson, Note 2). Other equity models are taken up in the discussion.

In this model, the state of equity for two persons, A and B, is defined by the equality of two proportionate ratios:

$$I_A/(I_A + I_B) = O_A/(O_A + O_B), \quad (1)$$

where I_A and I_B are the inputs for Persons A and B, and O_A and O_B are their corresponding outcomes.

With a fixed amount T to divide between A and B, Equation 1 becomes

$$O_A = [I_A/(I_A + I_B)]T. \quad (2)$$

Thus, A's fair share is just A's proportionate input. This model, however, assumes that I_A and I_B are one-dimensional. The theoretical problem concerns multidimensional input.

In the present experiments, information was given about two input dimensions: effort (E), or how hard the person tried, and performance (P), or how much the person actually accomplished. The rule of *input integration* could then be written as an adding-type model:

$$I_A = P_A + E_A, \quad I_B = P_B + E_B.$$

Weight parameters, w_P and w_E, are omitted for convenience, since they are effectively absorbed in the units of the scales of P and E. Substitution of these values into Equation 2 yields the model for input summation:

$$O_A = [(P_A + E_A)/(P_A + E_A + P_B + E_B)]T. \quad (3)$$

Under *equity integration*, separate equity calculations are made for performance and for effort, and these two equity ratios are then integrated. Under an averaging rule,

$$O_A = w_P[P_A/(P_A + P_B)]T + w_E[E_A/(E_A + E_B)]T. \quad (4)$$

Here, w_P and w_E are the relative weights associated with the two input dimensions, with $w_P + w_E = 1$.

It is simple to test between input summation and equity summation because they predict quite different data patterns. For example, Equation 4 implies that P_A and E_A combine additively because they are separated by a plus sign. The corresponding two-way factorial graph should thus exhibit a pattern of parallelism.

In contrast, Equation 3 implies that P_A and E_A combine nonadditively because they are separated by a division sign as well as by a plus sign. In this particular case, the corresponding two-way factorial graph should exhibit the pattern of a diverging fan of curves.

This two-way $P_A \times E_A$ graph thus provides

a simple sign to diagnose which, if either, of the two integration rules underlies the overt judgment. Other two-way interactions may be analyzed in the same way. This method of diagnosis requires some care, because the theoretical deviations from parallelism may be too small to detect under certain conditions. With due care, however, these two-way data patterns can be used to delineate the structure of the underlying integration processes.

Method

The subjects received information about the inputs of two persons, A and B, who had worked together on a common task. This input information specified effort (how hard A and B had tried) and performance (how much A and B had actually accomplished). The subject's job was to divide a fixed reward fairly between A and B on the basis of their inputs. Judgments were made on a 200-mm graphic scale labeled "Person A" and "Person B" at the ends.

Experiment 1

In Parts 1 and 2, the five levels of performance and effort were specified as follows: extremely above average, above average, average, below average, and extremely below average. The input information for each judgment was typed on an index card, and the deck of cards for each design was presented in a different shuffled order for each subject. Preliminary practice was given for each design. Subjects were 20 student volunteers from introductory psychology classes who received extra class credit for their services. They were run individually, served in all four designs, and made one judgment to every stimulus combination.

Part 1. Two 5×5 designs were used, the first of which specified the performances of A and B and the second of which specified the efforts of A and B. The first design was presented twice, with the first presentation serving as added practice, and the second design was presented once.

Part 2. One 5×5 design was used, in which both the performance of A and the effort of A were varied. Subjects were told that B had worked at the task but that they would not be informed of what B had done.

Part 3. One 3^4 design was used. Both performance and effort were specified for A and B. Except for a difference in the levels (namely, above average, average, and below average), the procedure was the same in this part as in Parts 1 and 2.

Experiment 2

This experiment had two main purposes. The first was to replicate the main design of Experiment 1 (Part 3) with more extreme levels of the stimuli. The second was to attempt to induce a strategy of input summation by making the input information homogeneous. By presenting two pieces of performance information about each person, it was thought that subjects would integrate this homogeneous information into a preliminary judgment of deservingness for each person and then make an equity division based on these two deservingness values.

Each factor had three levels in all designs, namely, very much above average, average, and very much below average. Subjects were 32 new subjects from the same pool as in Experiment 1. General procedure was similar to that of Experiment 1.

Part 1. Two 3^4 designs were used. In one, performance and effort were specified for A and for B, as in Part 3 of Experiment 1, except for the change in the phrases used to define the levels. In the other, two performances from separate and independent days were specified for A and for B. For each design, four examples were used as part of the instructions. These were followed by four end anchors and then 18 representative trials from the regular design. The order of presentation of these two designs was balanced across subjects.

Part 2. Two 3^2 designs were used. In one, performance was specified for A and for B. In the other, performance was specified on 2 separate and independent days for A, and B's performance over the 2 days combined was specified as average.

Results

The main goal in the data analysis was to test the two alternative rules, input integration and equity integration. These two rules predict quite different data patterns. These data patterns, especially the two-way factorial plots, may be used to diagnose which, if either, model underlies the observed judgments. Accordingly, the main exposition will be based on the visual appearance of the factorial graphs from the four-factor designs. Technical aspects of the model analyses are considered in more detail in a separate section.

Effort and Performance: Experiment 1

Theoretical interest centers on the two-way factorial graphs in the top layer of Figure 1. There are six graphs in this top layer, one for each two-way interaction in the main design. The two on the left have the shape of a slanted barrel; the remaining four exhibit parallelism. These six patterns of data must be related to the theoretical predictions.

Equity integration. The hypothesis of

equity integration provides a complete account of these data. All four panels on the right are predicted to be parallel by the reasoning given in connection with Equation 4 in the introduction. To illustrate, consider the third graph in the row. This shows that the fair share for A is an inverse function of B's performance (listed on the horizontal axis) and a direct function of A's effort (listed as curve parameter). From Equation 4, B's performance (P_B) and A's effort (E_A) combine additively, since they are separated by a plus sign. Accordingly, the theoretically expected shape is one of parallelism, and that is verified in the graph. Exactly the same reasoning applies to the three graphs farther to the right because each represents effort for one factor, and performance for the other.

The slanted barrel shapes of the two graphs at the left also agree with equity integration. To illustrate, consider the leftmost graph. It shows that the fair share for A is an inverse function of B's performance (listed on the horizontal axis) and a direct function of A's performance (listed as curve parameter). The barrel shape reflects the basic equity ratio, $P_A/(P_A + P_B)$, in Equation 4 (e.g., Anderson & Farkas, 1975; see also below). In the same way, the barrel shape of the second left graph reflects the basic equity ratio, $E_A/(E_A + E_B)$.

All six two-factor graphs thus agree with predictions from the hypothesis of equity integration. This hypothesis also predicts that the higher-order interactions are zero, a prediction that was largely supported, as noted below.

Input integration. The hypothesis of input integration disagrees with four of the two-way graphs in the top layer of Figure 1. It predicts that the two leftmost graphs should be very nearly parallel, whereas they actually show a barrel shape. It also predicts that the two rightmost graphs should form converging or diverging fans, whereas they are nearly parallel. Only the near parallelism of the two middle graphs agrees with prediction. These data, therefore, are sharply inconsistent with the hypothesis of input integration.

It needs mention that Equation 3 for input integration in principle predicts nonparallelism for all six graphs in Figure 1. In certain cases, however, predicted deviations from parallelism may be negligible, as for the four leftmost graphs of Figure 1. And although not of present concern, parallelism can also obtain when only two levels of each variable are employed (Anderson & Butzin, 1978). Un-

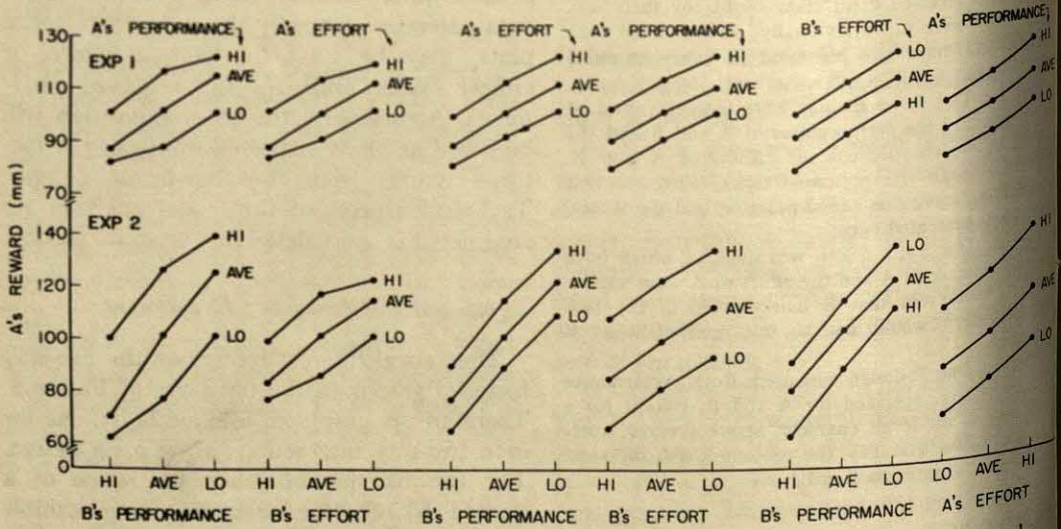

Figure 1. Mean reward allotted to Person A as a function of several stimulus variables. (Top and bottom layers show graphs of the six two-way interactions from corresponding designs of Experiments 1 and 2, respectively. HI = high; AVE = average; LO = low.)

fortunately, the algebraic structure of Equation 3 is not very informative about the sizes of the interactions. Accordingly, it appears necessary to use numerical analysis, as illustrated below in the section on model analysis.

Goodness of fit. Formal tests of the model may be obtained directly from the analysis of variance. Because of its theoretical importance, the complete analysis is presented in Table 1. Of primary interest are the F ratios for the two-way interactions: These F ratios test for deviations from parallelism for the two-factor graphs in the top layer of Figure 1. The Fs for the two leftmost graphs are 32.68 and 18.07, $p < 10^{-9}$. The sizes of these F ratios reflect the high reliability of the data, which allows ready detection of what are rather small deviations from parallelism. The other four graphs, in left-to-right order, correspond to nonsignificant Fs of 1.47, .67, .19, and 2.24, respectively. These tests thus confirm the above graphical analysis and support the hypothesis of equity integration.

Equity integration also implies that the higher-order interactions should be nonsignificant. This implication follows from Equation 4, because any set of three factors contains two that are separated only by a plus sign. In fact, none of the three-factor interactions in Table 1 is significant. The four-factor F of 1.83 is technically significant, but it is small and did not seem meaningful. Overall, therefore, the data provide strong support for equity integration and clear evidence against input integration.

Effort and Performance: Experiment 2

Further support for equity integration is given by Experiment 2, which included a nearly exact replication of the main design of Experiment 1 considered just above. The two-way graphs are plotted in the bottom layer of Figure 1. Each of these graphs shows essentially the same pattern as the corresponding graph from Experiment 1 in the top

Table 1
Summary Analyses of Variance for Four-Way Designs

Source	Performance × Effort: Experiment 1: F	Performance × Effort: Experiment 2: F	Source	Performance × Performance: Experiment 2: F
A: Performance-A	149.58	298.85	A: Performance-A1	669.78
B: Performance-B	173.13	314.79	B: Performance-B1	509.04
C: Effort-A	111.57	71.33	C: Performance-A2	583.17
D: Effort-B	99.52	72.54	D: Performance-B2	535.16
M error	472.02	1667.70	*M* error	517.40
AB	32.68	40.93	AB	7.98
AC	2.24	1.07	AC	6.61
AD	.67	.24	AD	6.13
BC	1.47	.50	BC	12.04
BD	.19	3.84	BD	17.96
CD	18.07	23.12	CD	11.70
M error	73.44	180.05	*M* error	104.55
ABC	1.55	6.09	ABC	10.47
ABD	.37	5.10	ABD	6.46
ACD	1.55	2.22	ACD	11.69
BCD	.67	3.07	BCD	6.94
M error	72.39	167.03	*M* error	98.20
ABCD	1.83	5.91	ABCD	18.75
Error	65.91	153.09	Error	111.60

Note. Two-, three-, and four-way interactions have 4, 8, and 16 *df*, respectively. Each interaction has its own error term, with 19 and 30 times as many *df* in Experiments 1 and 2, respectively. Critical values of F at the .05 level are 2.51, 2.00, and 1.66, on 4/76, 8/152, and 16/304 *df*, respectively, and 2.45, 1.96, and 1.65, on 4/120, 8/240, and 16/480 *df*, respectively.

layer. The two leftmost graphs show the predicted barrel shape, and the four rightmost graphs show parallelism. Just as in Experiment 1, therefore, these data provide clear evidence against the hypothesis of input integration and strong support for the hypothesis of equity integration.

There is one difference between the two experiments in Figure 1. The graphs show greater vertical spread in Experiment 2 than in Experiment 1. Also, the performance–effort asymmetry is considerably larger, as can be seen by comparing the two leftmost graphs in each layer. These effects arise from the changes in the definition of the stimulus levels and do not require any qualification of the theoretical interpretation.

However, one complication arose in the statistical analysis for Experiment 2. Although the two-way interactions were much the same as in Experiment 1, Table 1 shows that the three-factor and four-factor interactions are all substantial, contrary to the equity integration model. At first it was thought that these ineractions represented a mild degree of input integration. However, more detailed analysis showed that the interactions predicted by input integration were much too small.

Similar patterns of interaction were also obtained in collateral work on children's judgments of equity (Anderson & Butzin, 1978). These data suggested the presence of a configural element within the basic strategy of equity integration. When A and B had equal performance (or effort), subjects appeared to place greater weight on effort (performance). Thus, a dimension of difference appeared to influence the judgment more than a dimension of no difference. When this configural assumption was incorporated into the model, it provided a remarkably good account of the data, as is shown in the more detailed model analysis below.

Performance and Performance: Experiment 2

The rule of input integration was expected to apply when the input consisted of two pieces of performance information about each person. Since these two pieces of input information are similar, it should be easy to integrate them to obtain a single value of deservingness for each person. These deservingness values would then constitute the effective input values for the equity division between the two persons.

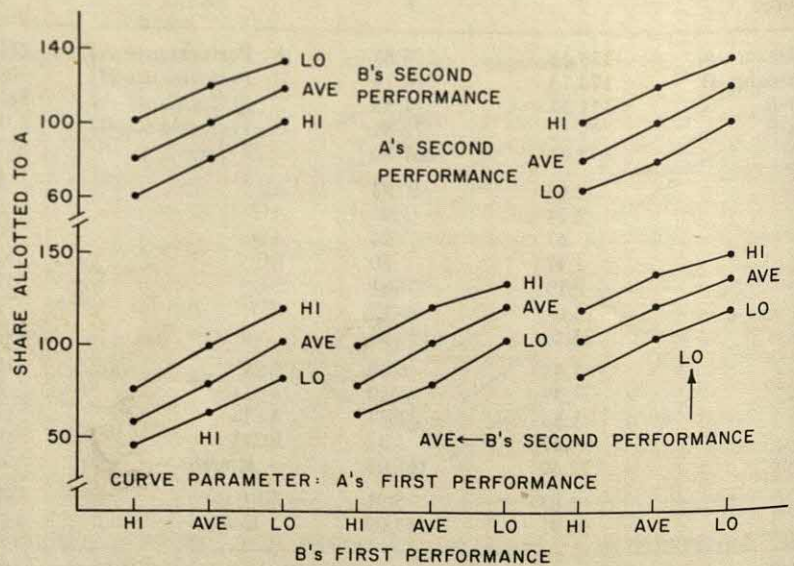

Figure 2. Mean reward allotted to Person A as a function of several stimulus variables, Experiment 2, Part 1. (Upper graphs show two representative two-way interactions; lower graphs show representative three-way interaction. HI = high; AVE = average; LO = low.)

The model of input integration provided an approximate account of the data, but there were small, worrisome discrepancies. Figure 2 gives an overview of the data. The graph at the upper right is representative of the four two-way interactions that involved one piece of information about each person. Theoretically, these graphs should be almost parallel. However, all four showed a slight barreling, and these deviations from parallelism were significant, as shown in Table 1.

A more serious difficulty for input integration is the pattern in the two-way graph in the upper left of Figure 2. This graph shows a mild convergence to the right, whereas the model predicts a moderate divergence. The arithmetic rationale for the divergence follows directly from the fact that both terms in this interaction, being performance levels of B, appear in the denominator of the model. The larger the value of one term, therefore, the smaller the predicted effects of the other. This discrepancy is reliable, since it also appeared for A. The given arithmetic rationale suggests that this discrepancy cannot be rectified by replacing the sum $P_A + E_A$ in Equation 3 by a more general input integration function, $f(P_A,E_A)$. These data therefore present a serious problem for the hypothesis of input integration.

A representative three-way interaction is shown in the lower layer of Figure 2. The left and right panels show mild divergence and convergence, respectively, whereas the center graph exhibits the barrel shape. The three panels are not geometrically congruent, and that incongruence produced a significant three-way interaction. The other three-way interactions had a similar pattern, a consequence of the symmetry in the design. Such a shift in pattern across the three panels, from divergence to barrel shape to convergence, is predicted by input summation, and it was initially thought that these three-way interactions provided good support for the model. However, more detailed analyses showed that the predicted interactions had substantially smaller magnitude than the observed interactions. Accordingly, these interaction patterns also present a difficulty for the hypothesis of input integration.

It deserves mention that the interaction patterns in Figure 2 provide a strong test of the input integration model of Equation 3, because that model has only two free parameters in the present experimental design. All four performance factors in the design are equivalent by symmetry, and the value of the middle level may arbitrarily be set equal to unity. Thus, the only two free parameters are the values of the high and low levels of performance. Since these values are essentially determined by the main effects, the interaction patterns provide clear tests of the model. It is possible, of course, that some configural assumption similar to that considered above would resolve the discrepancies. However, several attempts in this direction met with little success. Even though the discrepancies are small, therefore, they raise a serious question about the validity of the hypothesis of input integration.

A natural question is whether the rule of equity integration, which did well in the other main design, might also apply to the data in Figure 2. That this is not the case may be seen by comparing the two-way graphs between Figures 1 and 2. In Figure 2, all four graphs that included one piece of information about each person had the same slight barrel shape shown in the upper right. In Figure 1, however, the four graphs that included one piece of information about each person are the four leftmost graphs in either layer. These do not all have the same shape. Further, none of them is overly similar to the upper-right graph in Figure 2. From this comparison alone, it is clear that the rule of equity integration does not account for these data.

It is worth noting that a simple linear, adding–subtracting model would describe the data rather well, for the deviations from parallelism in Figure 2 are visibly small. For practical applications, at least, an adding-type model could provide a good approximation. Of course, that does not mean that the underlying integration process is basically additive (Anderson & Shanteau, 1977), although the possibility that the subjects tended to simplify the task in this manner deserves consideration (Shanteau & Anderson, 1972).

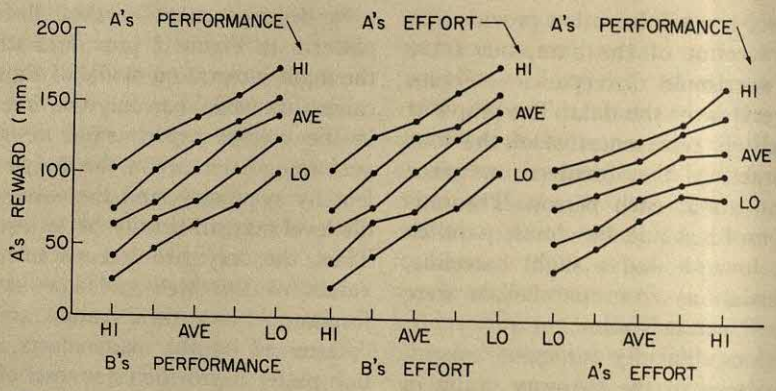

Figure 3. Mean reward allotted to Person A as a function of several stimulus variables. (Each panel represents one of the two-way designs of Experiment 1. HI = high; AVE = average; LO = low.)

Other Tests of the Equity Ratio Model

Both experiments contained designs in which the equity judgment was based on two pieces of information. These data do not bear on the main question of input integration, but they are relevant to the basic ratio model of equity theory given by Equations 1 and 2.

The results from the three designs of Experiment 1 are given in Figure 3. These graphs show little or no sign of the slanted barrel shape that is predicted by the basic ratio model. Indeed, each panel appears to be roughly parallel, as though an adding-type integration obtained. The deviations from parallelism are statistically significant in each case, $F(16, 304) = 2.72$, 4.04, and 3.99 in the three respective graphs. However, no pattern is apparent in these deviations, and they certainly do not follow the theoretical barrel shape.

A different picture was found in Experiment 2, as can be seen in Figure 4. Here both graphs show a clear barrel shape, in agreement with the equity model. The deviations from parallelism are highly significant, $F(4, 124) = 17.20$ and 24.86 in the two respective graphs. The basic model of Equation 2 gave a good fit to these data, as is shown below.

The five graphs of Figures 3 and 4 give a mixed picture on the equity ratio model. The data of Experiment 2 support the ratio model,

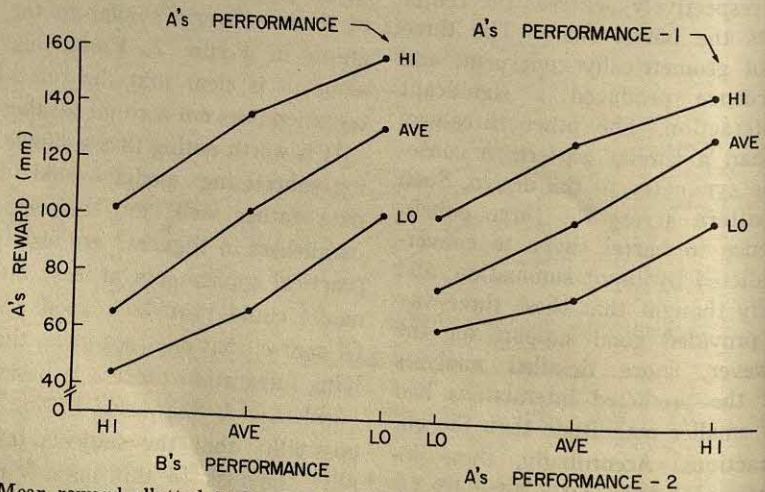

Figure 4. Mean reward allotted to Person A. (Each panel represents one of the two-way designs of Experiment 2. HI = high; AVE = average; LO = low.)

whereas those of Experiment 1 appear to support an adding-type formulation. Of course, the ratio model was not expected to hold for the case of heterogeneous information, namely, the Performance-A × Effort-A design in the rightmost panel of Figure 3. Similar results had been obtained by Anderson (1976a, Figure 3), and those results had led to the hypothesis of equity integration that was studied in the present experiments. However, the other two graphs of Figure 3 represent homogeneous stimulus information, and the apparent failure of the ratio model in these two cases is more disturbing.

One possible source of this difference in results lies in the different ordering of the two-way and the four-way designs in the two experiments. The two-way designs came first in Experiment 1, last in Experiment 2. It is possible, therefore, that the extended practice at integrating four pieces of information produced a tendency to use a ratio model that

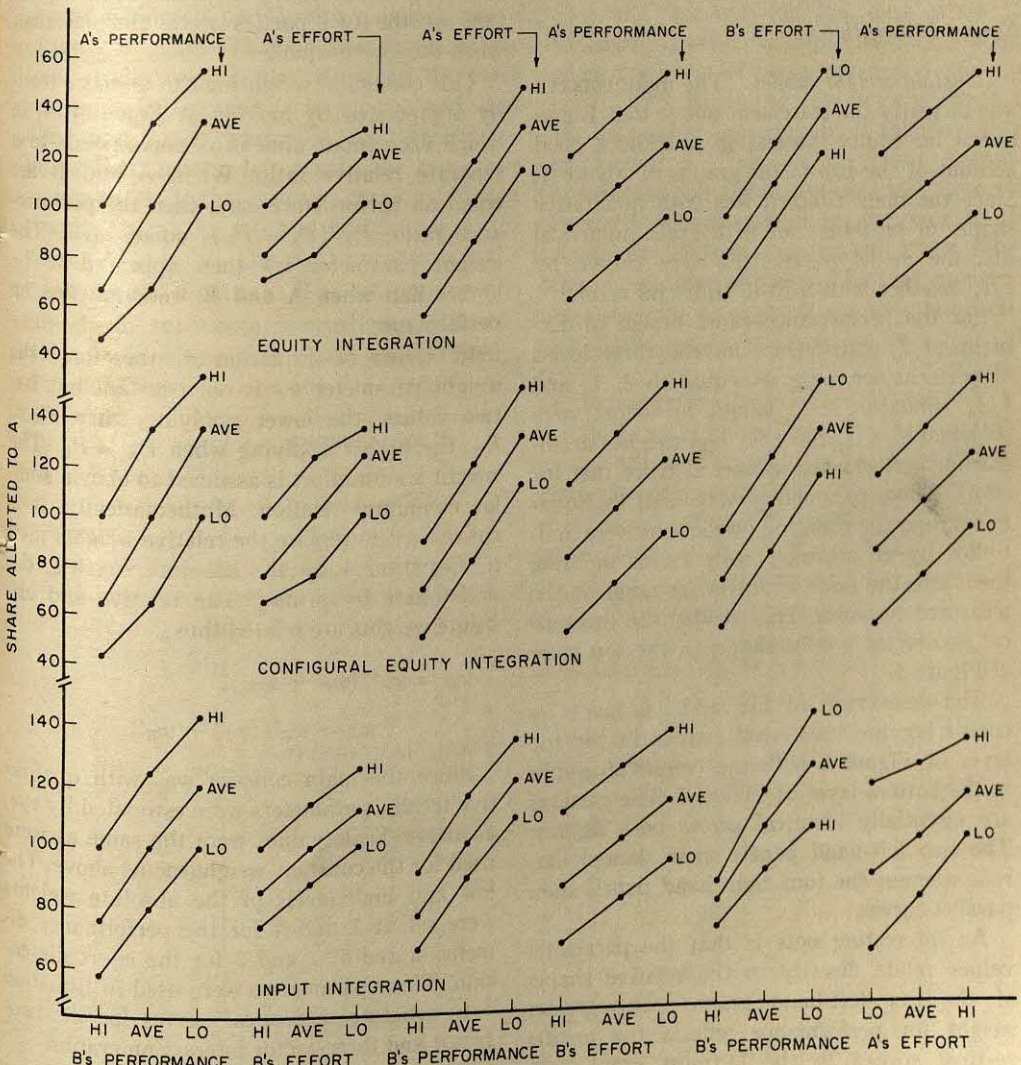

Figure 5. Theoretical predictions of two-way factorial graphs for the performance–effort design, Experiment 2. Top layer: Predictions from constant-weight equity integration. Middle layer: Predictions from configural-weight equity integration. Bottom layer: Predictions from input integration. (HI = high; AVE = average; LO = low.)

carried over to the later two-way designs in Experiment 2. When these two-way designs came first, as in Experiment 1, a simpler adding-type strategy may have prevailed.

Model Analyses

This section presents the more detailed analyses for the models that have been discussed above. For simplicity, only the data of Experiment 2 will be explicitly considered.

Equity Integration

Constant-weight model. The main concern was to verify the statement above that Equation 4 for equity integration provides a good account of the two-factor graphs of Figure 1. Since the main concern was with qualitative shapes or patterns, not with exact numerical fits, the model parameters were chosen by eye, together with a little trial and error.

For the performance–effort design of Experiment 2, scale values for the three levels of performance were set equal to 3, 1, and 1/3; similarly, scale values for effort were set equal to 4, 1, and 1/4. The weight parameter for performance was set at twice that for effort. These parameters were used in Equation 4, and the resulting predictions were multiplied by an arbitrary scale factor to bring them into the same approximate range as the measured response. This yielded the theoretical two-factor graphs shown in the top layer of Figure 5.

The assessment of the model is made by comparing the theoretical graphs in the top layer of Figure 5 with the empirical graphs in the bottom layer of Figure 1. The patterns are essentially identical across both figures: The two left-hand panels show slanted barrels, whereas the four right-hand panels show parallel curves.

An interesting note is that the parameter values relate directly to the relative shapes of the two left-hand graphs. The greater weight for performance reflects the greater vertical spread in the leftmost graph; the greater range of scale values for effort reflects the greater proportionate barreling of the next-to-left graph. Extreme levels of effort thus appear to have greater valence but less influence than extreme levels of performance.

Configural-weight model. Although Equation 4 for equity integration provided a good account of the two-factor graphs, it failed to account for the three-factor interactions that appeared in Experiment 2. Inspection of the data suggested that these three-factor interactions resulted from configural weighting. Each input dimension seemed to have greater influence on the equity division when the inputs of the two parties were unequal than when they were equal.

This configural weighting can be more readily appreciated by looking at Equation 4, in which each input dimension corresponds to a separate relative ratio. When A and B are equal on performance, say, then the performance ratio, $P_A/(P_A + P_B)$, equals 1/2. The weight parameter w_P then appeared to be lower than when A and B were unequal on performance.

In terms of Equation 4, therefore, the weight parameter w_P is not constant but has two values, the lower applying when $P_A = P_B$, the higher applying when $P_A \neq P_B$. The weight w_E for effort is assumed to obey a similar configural relation. Mathematically, it is convenient to replace the relative weights used in Equation 4 by the absolute weights, denoted here by primes. The relative and absolute weights are related thus:

$$w_P = w_P'/(w_P' + w_E'),$$

$$w_E = w_E'/(w_P' + w_E').$$

Since the main concern was with qualitative trends, parameters were estimated by eye, as above. Scale values were the same as were used for the constant-weight model above. The low and high levels of the absolute weights were set at 2 and 4 for the performance dimension and at 1 and 2 for the effort dimension. These parameters were used in Equation 4 to generate theoretical curves for the two-factor and three-factor interaction graphs.

The predicted two-way graphs are shown in the middle layer of Figure 5. Each two-way graph has the same shape as the corresponding graph from the constant-weight model

just above. Thus the configural-weight and constant-weight models yield virtually identical two-factor patterns. This pattern similarity comes about because the performance and effort dimensions are represented by separate ratio terms in Equation 4.

The main purpose of the configural model was to account for the three-factor interactions. This it does in remarkable detail. One of the empirical interactions is shown as the three 3×3 graphs in the upper layer of Figure 6. All three graphs show the same basic shape: a slanted barrel with a middle curve of greater slope. That is the shape of the basic equity ratio model. However, the three graphs differ somewhat in shape, and that difference is the source of the three-factor interaction. In the left graph, the top curve is bowed, but the bottom curve is almost straight; also, the top and bottom curves diverge to the right. The right graph shows the complementary pattern: The bottom curve is bowed, the top curve is nearly straight, and the two curves converge to the right. Finally, the center graph shows the pure form of the basic equity ratio model.

The theoretical predictions from the configural-weight model are shown in the lower layer of Figure 6. These have virtually the identical pattern as the data. The other three-factor interactions all had similar shape and were accounted for in the same manner. Thus, the configural-weight model for equity integration provides a detailed account of the main patterns of the data.

It is worth adding that the configural model does not account for the data when the weighting is reversed to use the larger weight when the levels of performance and effort are equal. This weighting reverses the shape of the leftmost predicted graph in the lower layer of Figure 6. The bottom curve becomes bowed, the top curve straight, and these two curves converge instead of diverging to the right; the rightmost predicted graph shows the complementary changes. The configural weighting is thus quite sensitive to specific pattern features in the data.

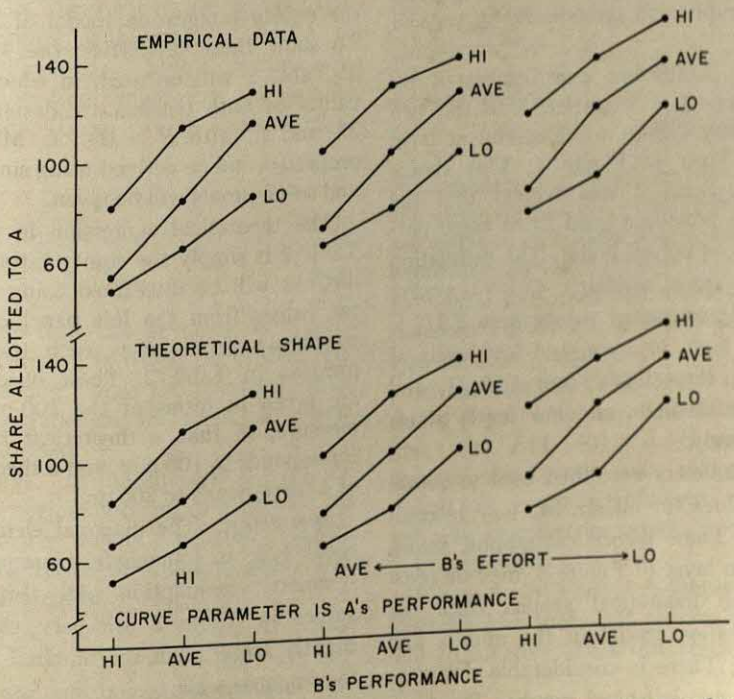

Figure 6. Comparison of observed three-way interaction with predictions from configural-weight model of equity integration. (HI = high; AVE = average; LO = low.)

Input Integration

One remaining question in the model analysis is whether the hypothesis of input integration can account for the data from the main designs that included information about both performance and effort. The model for equity integration gave a good account of these data, but perhaps the model for input integration could do the same.

To obtain a definite answer to this question, an exact fit of the model was made in the following way. Scale values for the medium levels of performance and effort were both set equal to unity; this is no restriction, since it merely sets the scale units. The weights are not identifiable parameters in this model, since they are absorbed into the scale units and so need not be estimated. Further, the scale values for Persons A and B are the same by virtue of the symmetry in the design. Thus, there are only four free parameters, the high and low levels of performance and of effort. The values of these four parameters are determined essentially by the sizes of the main effects. Accordingly, the shapes of the two-factor graphs will provide strong tests of the model.

The four parameters were estimated by fitting the model of Equation 3 to the two center two-way graphs for Experiment 2 in the bottom layer of Figure 1. This choice was made because it was evident that the model would provide a good fit to these particular data, as indeed it did. The estimation was done using Chandler's (1969) STEPIT program. The estimated values were 2.32, 1, and .33 for high, medium, and low levels of performance, respectively, and 1.69, 1, and .56 for high, medium, and low levels of effort, respectively.

These parameters were then used to obtain predicted values for all six two-way interaction graphs. These theoretical graphs, shown in the bottom layer of Figure 5, may be compared to the theoretical graphs from the equity integration model in the middle and upper layers. There is considerable disagreement for the two left-hand graphs: These exhibit the slanted barrel shape in the upper layers, but are virtually parallel in the bottom layer. There is also considerable disagreement for the two right-hand graphs: These are virtually parallel in the upper layers, but are markedly nonparallel in the bottom layer. Since the theoretical graphs for equity integration fit the data very well, it follows that the model for input integration fits very ill.

Configural-weight versions of the model for input integration were also considered, but these did not seem to give much improvement. It would seem that the algebraic structure of the model for input integration precludes a fit to these patterns of response.

Some Properties of the Equity Ratio Model

The relative ratio model of Equation 2 has some interesting mathematical properties when the two persons are treated symmetrically. These properties provide a basis for exact tests of fit and also for estimating the effective stimulus values of the inputs. These properties hold both for Equation 2 and for the two corresponding two-factor graphs of the equity integration model of Equation 4. To show these properties, the 3×3 design of Table 2 will be used, in which the input values of both persons are designated as H, M, and L, with $H > M > L$. Most of these properties can be derived using simple algebra, and so no proofs will be given.

The theoretical expression in each cell of Table 2 is simply the equity ratio. These predictions will be illustrated using the numerical values from the left panel of Figure 4, which are listed below each theoretical expression in Table 2. These observed values are given in terms of the 200-mm response measure, so that a theoretical ratio of 1/2 corresponds to 100 mm, and a theoretical ratio of 1 corresponds to 200 mm.

Symmetry. The diagonal elements should equal 1/2, an immediate consequence of the symmetry assumption. All three observed values in Table 2 are very close to 102, slightly larger than the nominal midpoint of the response scale.

Complementarity. Entries in cells that are symmetrically located about the main diag-

Table 2
Theoretical Analysis of Ratio Model, Symmetrical Case

Row level	Column level: H	M	L
H	(a) $H/(H+H)$ 101.9	(b) $H/(H+M)$ 137.2	(c) $H/(H+L)$ 157.8
M	(d) $M/(M+H)$ 65.3	(e) $M/(M+M)$ 102.2	(f) $M/(M+L)$ 133.0
L	(g) $L/(L+H)$ 43.7	(h) $L/(L+M)$ 67.8	(i) $L/(L+L)$ 102.1

Note. H, M, and L denote the three values of the input cues, assumed equal for the two parties. In each cell of the design, the ratio of values of input cues represents theoretical prediction; numerical value represents data from Experiment 2, Part 2. Letters a–i are used for identification in text.

onal should add to unity. In Table 2, therefore,

$$b + d = c + g = f + h = 1. \quad (5)$$

The observed sums are 202.5, 201.5, and 200.8, respectively, slightly greater than the theoretical value of 200. Complementarity is also an immediate consequence of the symmetry assumption. These data, like those just noted, support the further use of the symmetry assumption for this task.

Parallelism subtests. Table 2 contains three 2×2 subtables that should obey the parallelism prediction. These can be designated as follows:

$$\begin{aligned} a - d &= b - e, \\ e - h &= f - i, \\ a - g &= c - i. \end{aligned} \quad (6)$$

Each of these tests can be made as a 2×2 analysis of variance in which the critical term is the interaction. Since the observed deviations from parallelism are small, no formal test was performed.

Barrel shape. In the interaction tests, discussed in a previous section, considerable emphasis was placed on the prediction of a barrel shape. In terms of Table 2, the barrel shape is equivalent to

$$b - h > a - g = c - i. \quad (7)$$

The effect was substantial, since the difference on the left is 69 mm, and the two differences on the right are 58 and 56 mm, respectively. The mean net difference is thus 12 mm, considerably larger than the difference of 3.5 mm that would be required to reach significance.

An asymmetry. There is also an interesting asymmetry that is implied by the ratio model, though its size and sign depend on the exact values of the parameters. For the 3×3 design, the middle curve will generally have greater slope than the top and bottom curves. In terms of Table 2, this asymmetry is measured by

$$(c - f) - (d - g) = (HL - M^2)/(H + M)(M + L). \quad (8)$$

Accordingly, the expression on the left has the same sign as $HL - M^2$. Since M can be set equal to 1 without loss of generality, the expression on the right will be positive when $H > 1/L$. This condition was satisfied by the parameter estimates below, though the effect was not overly large.

In the data of Table 2, $c - f = 24.8$ mm, and $d - g = 21.6$ mm. The difference of 3.2 mm, with $F(1, 30) = 3.47$, was somewhat short of the 3.5-mm value that would be required to reach significance. Considerably stronger asymmetries appear in many of the graphs in Figures 1 and 2.

Parameter-free test. A simple test of fit is available that does not require estimation of any parameters. This test rests on the relation,

$$c/(1 - c) = b/(1 - b) \times f/(1 - f). \quad (9)$$

To perform this test, the terms on the left and right were calculated for each subject, and a t test was applied to the 32 difference scores. The mean difference of .2 did not approach significance, which supports the model. It should be noted, incidentally, that using the means from Table 2 in the expression above would introduce a small bias, since, in general, the ratio of the means is not the mean ratio.

Direct estimation of parameters. Three parameters appear in Table 2, but one of them can be set to any convenient value. This reflects the fact that multiplying all three parameters by a constant does not change the values of the ratios in the model. Accordingly, M was set equal to 1.

An estimate of H is then obtainable by equating the theoretical and observed values in Cell b of Table 2. This yields $H = 2.17$. Similarly, equating the theoretical and observed values in Cell h yields an estimate of $L = .52$. These estimates are not the best, because they do not use all of the data. Also they suffer a slight bias relative to the mean of the corresponding individual estimates. However, they differ little from the improved estimates discussed next, and they would be adequate for many purposes. For example, the mean magnitude of the discrepancies between the observed means of Table 2 and the values predicted from the estimates given above was only 1.4 mm.

Improved parameter estimates. The parameter estimates will be more stable when they are based on all of the data. Such estimates were obtained by fitting the ratio model separately to each subject's data, using a least squares criterion. Owing to the nonlinear nature of the model, an iterative procedure is required, and accordingly, Chandler's (1969) STEPIT program was used. The mean values of the estimates of H and L were 2.15 and .53, respectively—quite close to those obtained by the less efficient direct method given above. The mean magnitude of the nine deviations between the mean observed and the mean predicted value was only 1.2 mm.

Goodness of fit. Getting an exact statistical test of the ratio model is complicated by the nonlinearity, which prevents an exact tally of the degrees of freedom used in estimating the parameters. Fortunately, this complication can be circumvented using a new test procedure introduced by Leon and Anderson (1974). In brief, predicted values were obtained for each subject based on the parameter estimates for that subject. A 3×3 matrix of deviation scores was then obtained for each subject, and these data were tested in an ordinary repeated measurements design. The model implies that rows, columns, and interaction should all be nonsignificant in this analysis, and that prediction was supported by the results: The corresponding F ratios were $F(2, 60) = .15$, $F(2, 60) = .57$, and $F(4, 120) = 2.07$. On the basis of this exact test of goodness of fit, therefore, the ratio model does rather well. This one set of data is only illustrative, of course, but the same methods can be used more generally. With the iterative procedure, parameter estimation and the goodness-of-fit test do not require the assumption of symmetry.

Discussion

Theoretical Implications

Input integration versus equity integration. Multidimensional input is characteristic of everyday equity judgments. Rarely are such judgments made on the basis of a single piece of information. Typically, they entail the use of different kinds or types of information. That creates an obvious difficulty, noted in the introduction, in dividing a one-dimensional outcome in proportion to a multidimensional input.

This problem has been largely avoided in previous discussions of equity by the attractive assumption of input integration. The multiple aspects and dimensions of the stimulus field are assumed to be integrated to form one overall "deservingness" value. The complex stimulus field is thus reduced to a one-dimensional, effective input that mediates the division. Unfortunately, this assumption of input integration ran into difficulty in its first experimental test (Anderson, 1976a, Part 3, p. 295). The present results confirm the

difficulty and indicate that the hypothesis of input integration has limited applicability.

The alternative hypothesis of equity integration has the advantage that it does not require integration of qualitatively heterogeneous dimensions of input. Instead, each input dimension acts independently to determine its own implicit equity division. These implicit divisions, which are themselves qualitatively similar, are then integrated to determine the overt equity division.

This assumption of equity integration did remarkably well for heterogeneous input dimensions (performance and effort) in the present experiments. The one complication, from the higher-order interactions in Experiment 2, seemed to be easily handled in terms of configural weighting. The generality of the present results certainly needs to be assessed, using other scenarios, more than two dimensions of input, and more than two parties. As they stand, however, these data provide strong support both for the hypothesis of equity integration and for the basic relative ratio model.

Unfortunately, equal success cannot be claimed for the case of homogeneous input dimensions (actual performance on two occasions). The hypothesis of input integration had been expected to hold in this case, and the model predictions were verified to a good numerical approximation. Nevertheless, the pattern of discrepancies suggested that the underlying cognitive algebra was different than assumed in the model. Indeed, a linear model based on simple adding and subtracting of the four input dimensions did about as well.

This difficulty with the model for input integration is perplexing. Although the problem of integrating input for a single person has not received much explicit study, there seems little doubt that subjects can do this (see Anderson, 1978a, pp. 40ff). Also, the basic relative ratio model for division between two persons did well for the case of heterogeneous input dimensions, as already noted. Simple concatenation of these two operations would yield the input integration model. In further work on the problem of input integration, therefore, it may be useful to require initial judgments of deservingness about each separate party. That requirement would presumably force input integration as a preliminary to equity division and would help localize the discrepancies from the model.

Molar unitization. When input integration holds, then the effective input can be treated as a molar unit (Anderson, in press-a, in press-b; Anderson & Graesser, 1976) without regard for its molecular composition. No matter how intricate the stimulus field, no matter how complicated the process of input integration, the net result is a single value. This value can be quantified with functional measurement and used for description and for theoretical tests without knowledge of historical antecedents. When input integration holds, therefore, it can markedly simplify the theoretical analysis.

When equity integration holds, however, then input cannot be treated as a molar unit. Each dimension of input must be considered separately. That may be feasible when the input dimensions are under experimental control. However, it could be a serious problem in naturalistic situations in which the input dimensions may not all be known. Despite the present success of the rule of equity integration, the failure of molar unitization is disheartening because it points to unexpected complexities in equity theory.

One such complexity concerns the boundaries of equity theory. Some writers (e.g., Deutsch, 1975; Lerner, 1975) have assumed that parity (all persons treated alike) or need, for example, were distinct concepts that lay outside the boundaries of equity theory. Other writers (e.g., Walster et al., 1976) have claimed equity theory as a general theory, presumably encompassing such concepts as need, effort, and so forth. However, neither group of writers has discussed how this issue may be tested.

Equity theory does provide a simple conceptual test: If need affects input, then need lies within the domain of equity theory. This conceptual test would become operational if input integration held. Then the pattern of data could reveal whether need affected input in the same way as work contribution or acted as a separate force (Anderson, Note 2). But if equity integration holds, then need acts separately, regardless of whether it is a proper

determinant of input. Under equity integration, therefore, it may not be easy to progress beyond phenomenological speculation about the boundaries of equity theory.

Despite these disadvantages, the rule of equity integration does have one notable advantage in relation to the problem of multidimensional outcome (Farkas, 1977). In general, outcome is not one-dimensional. Besides money, it may include praise, status symbols, working conditions, and so forth. A simple rule of input integration would require that all outcomes be divided in the same proportion. However, a rule of equity integration makes direct allowance for weights that represent input–outcome relevance. Thus, more money might be given the person with the greater work contribution, more praise to the person who tried harder, and more status symbols to the person who needed them more. From this standpoint, therefore, the rule of equity integration may be conducive to a more just society.

Overview of Equity Models

The discussion above has been restricted to the equity model from information integration theory, as given by Equations 1 and 2 in the introduction. This section gives an overview of other models that have been proposed in equity theory, followed by a brief summary of negative evidence on the basic ratio assumption employed in many of these models. For simplicity, it will be assumed that inputs are one-dimensional and positive (see also Anderson, Note 2, p. 162).

Three ratio models. The relative ratio model from information integration theory (Equations 1–2) is closely related to ratio models proposed by Aristotle (quoted in Walster & Walster, 1975) and by Adams (1965). Aristotle's definition of equity is given by the equation:

$$O_A/O_B = I_A/I_B. \quad (10)$$

Adams defines equity by the equation:

$$O_A/I_A = O_B/I_B. \quad (11)$$

These models imply different psychological comparison processes. In Aristotle's model, the two ratios involve comparison of like quantities. In Adams' model, the two ratios involve comparison of unlike quantities. Algebraically, however, they are equivalent to each other and to the relative ratio model of integration theory. Equity judgments do not distinguish among these three models.

However, it is possible to distinguish among the three models by obtaining judgments of inequity (Anderson & Farkas, 1975). In these tests, both the relative ratio model and Aristotle's model did quite well. Adams's model, however, did quite poorly, an outcome that has been corroborated in an extensive study of unfairness judgments by Farkas (1977).

Walster, Berscheid, and Walster. Walster et al. (1976; see also Walster, 1975) defined equity with the following equation:

$$(O_A - I_A)/|I_A|^{k_A} = (O_B - I_B)/|I_B|^{k_B}, \quad (12)$$

where the ks are $+1$ or -1 according as $(O - I)$ and I have the same or opposite signs. This model was introduced in an attempt to avoid apparent paradoxes that arise with negative input for the three ratio models considered in the preceding subsection. However, simple thought experiments show that the Walster model also leads to paradoxes, even indeed with positive inputs and outcomes (Anderson, Note 2, p. 161; Note 3, p. 16).

To illustrate, let $I_A = 10$ and $I_B = 5$, in 2:1 ratio. With 18 units to be divided, an equitable distribution is clearly $O_A = 12$ and $O_B = 6$. The three ratio models and the Walster model all agree on this.

Now suppose that there are only half as many outcome units to be divided. It seems obvious that the outcome for each person should also be reduced in half. Indeed, the first three models imply $O_A = 6$ and $O_B = 3$. But the Walster model requires $O_A = 8$ and $O_B = 1$. It seems hardly just that B should lose 4 out of 5 input units, whereas A loses only 2 out of 10.

Finally, suppose that there are only 3 units to be divided. Then the Walster model not only denies that $O_A = 2$ and $O_B = 1$ is equitable, but claims that equity requires $O_A = 6$ and $O_B = -3$. Because B's input was less than A's, B is required to make an additional payment to A. Thus, B's net loss comes to

8 units, whereas A's net loss is only 4 units. This thought experiment shows that the Walster model cannot be valid.

Harris. A somewhat different approach to equity models has been taken by Harris (1976), who considers a number of formulas in terms of rational criteria that they might be expected to satisfy (e.g., outcome should be an increasing function of input). Only Harris's preferred "linear formula" (slightly amended by Harris, Note 4) is considered here. For a two-party division, it defines equity by the equations,

$$O_A = aI_A + r$$
$$O_B = aI_B + r, \qquad (13)$$

where the parameters $a > 0$ and r are the same for both parties, but may depend on I_A and I_B.

This formula is unsatisfactory because it can always give a perfect fit to two-party divisions. The formula is not truly linear because a need not and generally could not be constant across situations. In general, Harris allows a to be some arbitrary, unknown function of the inputs and outcomes of all the parties to a given division. Equations 13 are thus two equations in two unknowns and so can always be solved exactly for a two-party division. In the present two-factor designs of Figures 3 and 4, for example, Harris's formula would provide a perfect fit to every data point. These perfect fits do not support the formula, of course, but instead show that it is not testable with two-party divisions. Perhaps some theoretical foundation for the a parameters could be found that would allow a test similar to that allowed by the models discussed above. As long as the formula is not testable with two-party divisions, however, it does not seem to be very satisfactory.

Subjective values. As has been emphasized by Adams (1965) and by Walster et al. (1976), equity theory in psychology deals with personal values and feelings. In general, therefore, tests of equity models must be capable of measuring psychological values of input and outcome on true linear or ratio scales. Failure to recognize the need for subjective measures can undercut the theoretical reasoning.

This difficulty can be seen in the literature on children's judgments of equity. Nearly all this work has relied on physical counts as measures of input and outcome. Input might be measured by number of problems solved, for example, and outcome by number of candies received. Various theoretical interpretations rest on the implicit assumption that subjective values are proportional to these physical values. This assumption is arbitrary and uncertain, however, and so some of this work does not have any clear meaning (Anderson & Butzin, 1978).

It should be emphasized that many studies of equity do not require linear or ratio scales. A monotone, rank-order response scale can be entirely adequate for certain purposes (see, for example, Anderson, 1976b, p. 689), and it may not then be worthwhile to seek for linear scales. For other purposes, however, linear or ratio scales are vital. One reason for studying algebraic models of equity is that they can provide a base and frame for such measurement scales.

Evidence on the relative ratio model. Although the relative ratio model has done remarkably well in some situations, it has done more or less poorly in others. Existing data point to three areas of poor performance that deserve mention. The most severe discrepancies were obtained in the sole test in which total outcome was not a fixed sum. In this case, the model has a ratio form that implies a linear fan pattern of response. The obtained response pattern showed marked discrepancies from this theoretical linear fan (Anderson, 1976a, Figure 1 and p. 295; 1978b). A second kind of discrepancy appeared in Experiment 2 above for the task in which two pieces of similar performance information were given about each person. Although the rule of input integration was perhaps not too far off, the meaning and seriousness of the discrepancies remain unknown.

The third discrepancy is that rather similar tasks sometimes yield the theoretical pattern of a slanted barrel, but sometimes a pattern of approximate parallelism. Illustrations appear in Figures 3 and 4 above, and in Figures 2 and 3 of Anderson (1976a). Failure to get the theoretical barrel shape does not seem to

be due to lack of power. Although the obtained barrel patterns show only modest deviation from parallelism, they have typically been highly significant statistically. It is possible that the approximate parallelism results from a tendency to simplify the task by using adding or subtracting rules in place of the seemingly more difficult ratio rule. This is only speculation, however, for there is almost no evidence on the causes of this third kind of discrepancy.

This brief summary indicates that the cognitive algebra of equity (and inequity) is in an uncertain state. Still, the relative ratio model has had some substantial successes, and there is hope that the discrepancies will find a simple theoretical interpretation.

Race, Sex, and the Expression of Self-Fulfilling Prophecies in a Laboratory Teaching Situation

Marylee C. Taylor
Harvard University

The aims of the study were (a) to identify patterns of teacher behavior that vary with expectations for pupil ability and thus may mediate teacher expectancy effects and (b) to investigate ways in which pupil race and sex may interact with perceived pupil ability in affecting teacher behavior. For the experiment, 100 white female undergraduates enrolled in teacher training programs presented lessons to "phantom" students, who were alleged to be observing and responding from behind one-way glass. Race, sex, and ability manipulations were embedded in descriptions of these phantom pupils. Numerous verbal and nonverbal aspects of teacher behavior were recorded. Subjects with low-ability "pupils" taught less material, allowed less response opportunity, gave lengthier praise after successful performance, and showed less vocal nervousness. Particularly interesting Race × Ability interactions were found, showing that teachers direct most positive affect to high-ability black and low-ability white pupils.

In 1968 Robert Rosenthal and Lenore Jacobson published the report of a study demonstrating that experimentally manipulated teacher expectancies for pupil progress can affect pupils' intellectual growth. Subsequent research has provided steadily accumulating evidence of self-fulfilling prophecy effects in classroom education (Crano & Mellon, 1978; Rosenthal, 1973, 1976). One implication is that the much discussed relation between pupil academic achievement and such background characteristics as race and socioeconomic status may be partially attributable to teacher expectations for pupil performance.

Although little question remains about the existence of expectancy effects, there are gaps in our understanding of how these effects operate. The present study addresses two kinds of questions about the operation of teacher expectancy effects: First, what particular patterns of teacher behavior vary with expectations for pupil ability and thus may mediate the relation between teacher expectations and pupil performance? And secondly, how do teacher expectations about pupil ability interact with other pupil characteristics—particularly pupil race, and also pupil sex—in affecting teacher behavior?

Ability-Expectancy Effects

Systematic investigation of the mediation of teacher expectancy effects has been undertaken by a number of researchers, and an integration of these research findings has been presented by Rosenthal (1973). In his review, Rosenthal offers a four-factor "theory" of teacher expectancy mediation, naming four major categories of mediators, each suggested by at least five empirical studies to be related to pupil-ability expectations held by teachers. Rosenthal's *climate* factor represents general, noncontingent teacher warmth, communicated through such behaviors as smiling, head nod-

This article is based on a doctoral dissertation completed at Harvard University. The research was funded, in part, by the National Science Foundation.

The author would like to thank Robert Rosenthal for his support of this project and for his valuable assistance. The author is also grateful to Gloria I. Joseph, Judith A. Hall, and Michael P. Johnson for their generous contributions at various phases of this project.

Requests for reprints should be sent to Marylee C. Taylor, who is now at the Department of Sociology, The Pennsylvania State University, University Park, Pennsylvania 16802.

ding, leaning forward, and maintaining eye contact. Greater teacher warmth is generally directed to pupils for whom positive expectations are held. The second factor is *input*; teachers try to teach more material and more difficult material to their high-ability pupils. Represented in Rosenthal's *output* factor is the evidence that teachers encourage greater responsiveness from high-ability pupils. This may take such forms as offering more frequent response opportunities, asking harder questions, or being more patient in waiting for pupil responses.

Research evidence pertaining to Rosenthal's fourth factor, *feedback*, is more complex. In general, it seems to be the case that feedback is given more clearly and more consistently to high-ability than to low-ability pupils. There are qualifications, however: When criticism after unsuccessful performance is the feedback at issue, low-ability pupils have sometimes been the disfavored group; and particularly high levels of teacher praise have occasionally been found to be directed toward low-achieving and disliked pupils (Brophy & Good, 1974). Of the four categories suggested by Rosenthal, feedback seems to be the one most in need of conceptual and empirical clarification.

A goal of the present study was to examine effects of experimentally induced teacher expectations on behaviors representing all four of the mediation types Rosenthal suggests.

Pupil-Race Effects

Previous research provides substantial evidence for effects of pupil race as well as ability expectations on teacher orientation and behavior, with black children the recipients of the less desirable evaluations and treatment at the hands of (typically white) teachers. (See, for example, Antonoplos, 1972; Datta, Schaefer, & Davis, 1968; Leacock, 1969; Yee, 1968). Yet these studies focused on classroom teachers and their actual black and white pupils, so that pupil race was confounded with other pupil characteristics that could plausibly affect teacher orientation. Studies that have failed to find effects of pupil race typically employed a "phantom other" design, in which subjects were asked to rate written descriptions of imaginary black and white students (see Dietz & Parkey, 1969; Long & Henderson, 1974; Mazer, 1971; Miller, 1973), and there is reason for concern about generalizability. In a series of studies that attempted to address both internal and external validity concerns, safeguards against confounding with pupil race and realism were introduced into the design (Coates, 1972; Crowl & MacGinitie, 1974; Harvey & Slater, 1975; Jensen & Rosenfeld, 1974); in these, pupil-race effects were found, but the dependent variables were teacher ratings rather than behavioral measures. Thus, there do remain questions about the effect of pupil race per se on teacher behavior.

The Repression-of-Affect Hypothesis

An intriguing hypothesis specifying a pattern of incongruous race effects comes not from educational research but from a study of interracial interaction. Weitz (1972) administered a racial-attitude questionnaire to her subjects, and later obtained a number of measures of their orientation to a fictitious, soon-to-appear co-worker described to them as being either black or white. The most interesting aspect of the Weitz findings was negative correlations among some of her measures of white-to-black attitudes and behaviors. Weitz concluded that whites with negative racial feelings may, under pressures of a liberal environment, attempt to portray a pro-black posture but leak their underlying negative feelings in behaviors not amenable to conscious control. The result would be the emission of double messages, suggested (Bateson, Jackson, Haley, & Weakland, 1956) to be harder for children to handle than consistent negative messages. The repression-of-affect proposition is certainly important enough in its implications to warrant further testing.

The Interaction of Pupil Race and Ability

Central to the present project is the question of how pupil race may combine with ability expectations to influence teacher be-

havior. Most discussions of pupil-race and ability expectations assume a simple additive model: Whiteness and a high-ability label serve as two strikes in favor of a child, blackness and a low-ability reputation, two strikes against. A disturbing alternate possibility is, however, suggested by the findings of Rubovits and Maehr (1973). When these researchers assigned white university students to teach black and white children who had been randomly assigned labels of "gifted" or "nongifted," there was an interaction of race and ability in their effect on teacher behavior: The gifted label seemed to be an advantage for the white children but a disadvantage for the black children.

The Rubovits and Maehr evidence does not, however, stand without contradiction. Other studies have yielded results suggesting Race × Ability interaction in the other direction, with low-ability black pupils being the recipients of particularly negative teacher orientation (see Datta et al., 1968; Henderson & Long, 1973). In the case of these latter studies, however, the dependent measure has been teacher ratings rather than behaviors. Thus there remains the need to examine Race × Ability effects on teacher behavior, using a design that eliminates the possible confounding of pupil race with other factors. Such an examination was a major goal of the present study.

Pupil Sex and Its Interaction With Race and Ability

As a supplementary benefit, the study offered the opportunity to examine teacher behavior for evidence of pupil-sex effects. From their review of relevant research, Brophy and Good (1974) concluded that there is evidence of teachers' preference for female pupils, as well as evidence that teachers underestimate both the potential and the achievements of male pupils. However, they failed to find convincing evidence of favoritism toward girls in teacher behavior and concluded that previously noted pupil-sex effects on teacher behavior were accounted for by sex differences in the behavior of the children. The present study allowed reconsideration of the no-difference conclusion drawn from previous research on sex effects. Perhaps more interesting, it allowed examination of evidence regarding possible interactive effects on teacher behavior of pupil sex and ability, and of pupil sex and race, topics about which little is, as yet, understood.

Overview of the Study

The present study was designed to address simultaneously a number of the hypotheses and questions suggested by the literature reviewed here. White female undergraduates enrolled in teacher training programs were asked to teach two lessons to a phantom student, who was alleged to be observing and responding to them from behind one-way glass. On a light panel in the experimental room, the subjects received standard responses to their questions from their "6-year-old pupil," described as being either black or white, male or female, and of high or low ability. Numerous kinesic and paralinguistic measures of teacher behavior during the lesson presentation were obtained, along with measures of various aspects of teaching style as well as teacher ratings of the pupils.

The variety of behavioral measures in the present study, including representatives of each of Rosenthal's (1973) four factors, allowed for examination of effects of pupil characteristics on the patterning of those teacher behaviors suggested to be most important in the transmission of self-fulfilling prophecy effects in one-to-one teaching situations. This design allowed testing for interactive effects of ability expectations and pupil race on teacher behavior, without the possibility, present in the Rubovits and Maehr (1973) study, of confounding effects from actual differences in pupil behavior. Built into the present study was a direct search for evidence of Weitz's (1972) repression of affect in subjects teaching black "pupils": At the midpoint of the experimental session there was a manipulation of demand characteristics; half the subjects received a message designed to encourage attempts at problack behavior and thus to maximize the probability of leakage and the contradictory pattern Weitz discusses. Finally,

auxiliary questions, such as those regarding main and interactive effects of pupil sex on teacher behavior, were examined.

Method

Subjects

For the experiment, 105 white female[1] undergraduates at the University of Massachusetts, Amherst, served as subjects. All were either majoring in education or working for teaching credentials. All but 2 were upper-class students, all but 12 had practice teaching experience or the equivalent, and the majority were enrolled in elementary education programs. A few subjects volunteered in response to posted announcements of the study, but the vast majority were identified from university records and recruited by telephone. Recruits were told only that they would receive $2 compensation for 1 hour of participation in an experiment that would concern teaching.

Setting, Equipment, and Materials

The experimental room, in which the subjects performed their teaching task, was simply furnished with a long table, a rolling chair, a floor microphone to be used during lesson presentations, and an armchair and coffee table for the subjects' use during other phases of the experimental routine. Furnishings were positioned so that during their lesson presentations the subjects could sit at an angle from the unobstructed section of a one-way glass window into the observation room, facing the window but unable to see their own reflection in it. Beneath the observation room window stood a light panel on which the "pupil" responses were to be transmitted to the subjects. The panel contained 10 lights, labeled to represent 10 possible responses to the prescribed questions accompanying the lessons.

Two lessons were constructed for the experiment. Both concerned mathematics, and the two paralleled each other as nearly as possible. Each lesson contained four sections, the internal structure of the sections being identical. A given section contained the following: a statement of the concepts and definitions to be read to the "pupil" by the subject; a set of examples, half of which were illustrated; question-answering instructions to be read to the "pupil"; and a set of illustrated questions.

Standard response schedules were followed by an experimental assistant who controlled the light panel. For each lesson question, the schedule specified not only the response(s) to be given but also the latency of the response(s). (In some cases incorrect answers were given initially, and correct responses given only after repeated questioning; for such questions, the sequence of responses to be given by the experimental assistant was specified by the schedule.)

The lessons were constructed in consultation with a specialist in elementary mathematics education. Response schedules were constructed after pretesting the lessons on children the age of the alleged pupils of the experiment. Thus, the appearance of the lessons as legitimate educational vehicles and the plausibility of the allegation that an actual child was responding to the questions were maximized.

Experimental Manipulations and Design

The three major independent variables were manipulated through a Pupil Information Sheet, which contained pupil race, sex, and ability designations, embedded in other information. All pupil information (including age—6 years) was identical except for the pupil's name (John or Betty Powell), sex, ethnic origin (Afro-American or English American), and ability ("at the high end of the class range" and "in one of the highest classroom groups" or "at the low end of the class range" and "in one of the lowest classroom groups"). The awareness manipulation, designed to intensify demand characteristics and possible repression of affect, was included as part of a written reminder for the subjects to try to behave as if they were in a natural teaching situation. For those in the aware condition, this reminder was preceded by the statement: "A major purpose of this study is to compare the ways teachers behave toward black and white students."

A completely crossed repeated-measures design was used. Subjects in the 16 (Ability × Race × Sex × Awareness) conditions were measured twice on each of the dependent variables, once during each lesson presentation. In order to minimize the possibility that any effects of time or order would be confounded with those of the independent variables, assignment to experimental condition was performed within each block of 16 subjects scheduled for consecutive testing. Because some supplementary subjects were tested, and their data retained in the analysis, cell *n*s were slightly uneven, ranging from five to eight.

Procedure

As each subject was greeted by the (female) experimenter, she was presented with written materials containing instructions and an explanation that the research purpose was to examine certain aspects of teaching behavior in a situation where feedback from pupil to teacher was limited. The subject was then taken to the experimental room and left for 5 min to read the Pupil Information Sheet, which

---

[1] With four independent measures of central interest here, it was deemed infeasible to vary experimenter sex and race as well. White females were the group targeted for study because of their historical and continuing prevalence in elementary teaching. There is certainly the need for analogous investigation of black and male populations, an inviting task for the future.

contained the pupil race, sex, and ability manipulations; to review the materials pertaining to the first of the two lessons she would present (the order in which the two lessons were presented was simply alternated from one subject to the next); and, finally, to rate estimated lesson difficulty for the pupil. At the conclusion of this interval, the subject was signaled to move the rolling chair and floor microphone to a position of her choice alongside the large table, and to begin presenting the lesson to the pupil who was allegedly listening and watching through the observation room window. Lesson presentation involved proceeding through the sections of the lesson, repeating a sequence that consisted of exposition, optional presentation of illustrated or nonillustrated examples, and questioning pertinent to the material of that section. At the end of 10 min, the subject was signaled to conclude the lesson presentation, and was given 4 min in which to rate the learning and ability of the pupil.

At this point the subject read the reminder in which the awareness manipulation was included. Then the second lesson was presented, procedures for this parallel presentation being identical to those for the first.

Before being excused, the subjects completed a written manipulation check and probe for hypotheses about the nature of the experiment, and were paid the $2 compensation. Later, after all the subjects had been tested, a thorough debriefing letter was mailed to all the participants, and an announcement was made of a session at which the subjects could discuss the study with the experimenter.

Two assistants were present in the observation room during all testing sessions, one controlling recording equipment and the light panel that allegedly conveyed pupil responses to questions, and the other rating kinesic and proxemic behaviors of the subjects. When possible, the experimenter made independent ratings so that interjudge reliabilities could be computed.

As a safeguard against experimenter expectancy effects, all those at the research site were completely blind to subject condition, except in those cases where the subject used the name of her "pupil," thus revealing the sex of the "pupil" to the assistant who was performing auditory monitoring of the teaching sessions. This assistant was positioned so as to be shielded from visual cues, which might have biased responses on the light-panel controls. Analogously, the assistant performing proxemic and kinesic ratings was shielded from vocal cues, which might have contaminated the ratings.

Aside from the teacher ratings and the kinesic measures recorded by the rater positioned in the observation room, dependent measures were taken from the audio recordings of the teaching sessions. Most involved simple coding performed directly from the audiotapes, the exception being the voice ratings, which required a more elaborate procedure.

For purposes of obtaining voice ratings, four 3-sec clips of each subject's lesson presentation were excerpted, one from the beginning and one from the middle of each lesson presentation. These taped excerpts were content-filtered, a process in which certain frequencies are deleted from the recording, rendering the verbal content of the speech incomprehensible but preserving much of the tonal quality and rhythm of the speech. (For a more detailed description of this technique, see Rogers, Scherer, & Rosenthal, 1971). For raters, 16 female Harvard summer school students were recruited. The raters, half black, and half white, ranged in age from 18 to 21 years; eight had had some teaching experience. Each rater was presented with a stimulus tape containing half of the 3-sec excerpts, one excerpt representing each subject during each lesson presentation. During each of six playings of the tape, these judges rated the content-filtered excerpts on a dimension specified by the researcher.

Dependent Measures [2]

The climate factor. Rosenthal's (1973) climate factor was represented by four behavioral measures:

1. *Smiling* (number of smiles during three 1-min periods of a lesson presentation);
2. *Head nodding* (number of up-and-down head nods during three 1-min periods of a lesson presentation);
3. *Forward leaning* (seconds of leaning toward the observation room window during three 1-min periods of a lesson presentation);
4. *Vocal warmth* (mean of 16 rater judgments of content-filtered excerpts on a 9-point cold–warm scale, where warm is high).

The input factor. The input factor named by Rosenthal (1973) was represented by the following measure:

5. *Teaching pace* (number of nonoptional lesson segments presented during the 10-min session, coded so that for each of the four lesson sections, completion of all nonoptional segments would yield a score of 75).

---

[2] The dependent measures listed here are those to be discussed in the pages to follow. Their selection from a larger set was based on considerations of interpretability, theoretical import, nonredundancy, and empirical interest. Data collected but not discussed here include the following: a proxemic measure and kinesic measures of backward leaning and shifting; various indicators of the way in which teaching time was apportioned; measures of several kinds of assistance given during question-and-answer sessions; voice ratings on dimensions defined by the poles businesslike–personal, condescending–admiring, discouraging–encouraging, and not competent–competent; subjects' ratings of their pupils; and scores on a test of Afro-American history and culture administered to the subjects. Information about effects on these measures and relationships among them can be obtained from the author.

The output factor. Several assessments of the response opportunities offered the pupil were made, including:

6. *Impatience* (average number of times, per question asked, that the subject interrupted the "pupil" response, i.e., interrupted the latency period between question and response called for by the response schedule);

7. *Persistence after "pupil" errors* (percentage of correct answers obtained; since the response schedule dictated that correct answers could be elicited by repeating questioning, this is a measure of persistence in repeating incorrectly answered questions).

The feedback factor. The complexity of previous research findings concerning teacher feedback suggested that multiple measures should be used here. Five were employed: [3]

8. *Praise feedback incidence* (percentage of correct responses followed by explicit praise, e.g., "very good"; statements merely confirming the correctness of a response were not included);

9. *Praise feedback length* (average seconds spent praising correct responses per occasion on which such feedback was given);

10. *Incorrectness feedback length* (average seconds spent responding to an incorrect answer per occasion on which such feedback was given);

11. *Positive feedback omission* (percentage of correct responses followed by either silence or an ambiguous response);

12. *Negative feedback omission* (percentage of incorrect responses followed by either silence or an ambiguous response).

Vocal anxiety. In addition to the behavioral representatives of the four types of mediators suggested by Rosenthal (1973), included in the study were several indicators of another construct, vocal anxiety. Measures included the following:

13. *Speech errors* (total number of times a subject changed the course of a sentence in midstream, corrected herself, made obvious grammatical errors, mispronounced common words, misread sections of the lesson, or "got her tongue twisted");

14. *Pausing* (number of seconds of pausing during a lesson presentation, with 5 sec of silence used as the minimum criterion for a pause);

15. *Vocal nervousness* (mean of 16 rater judgments of content-filtered excerpts on a 9-point nervous-calm scale, where calm is high).

Inadvertent helpfulness. The final behavioral measure to be discussed here had not been planned but was suggested by the contents of the audiotapes:

16. *Helpful slips* (total number of times a subject made an apparent slip of the tongue and gave away the answer while trying to ask a question).[4]

Preliminary Analyses

Manipulation check. On the manipulation check instrument, administered at the conclusion of the study, 86 of the 105 subjects reported the appropriate ability level of their "pupil," all but two of the remaining responses being noncommittal. When asked about ethnic origin of their "pupils," 96 responded appropriately, 8 failed to answer, and 1 subject in the Afro-American condition reported "Anglo-Saxon." This last subject, who apparently misread the manipulation, was the only case excluded from the data analysis on the basis of the manipulation check; four others were excluded because of some deviation from standard experimental procedure. Thus, primary data analyses were carried out on data from 100 subjects.

The subjects' ratings of their "pupils" were used to assess the potency of the ability manipulation. The subjects had estimated "lesson difficulty for the pupil" and "pupil intellectual potential," in each case yielding a score from 0 to 130. Those in the high-ability condition estimated that the lessons would be easier for their pupils ($M = 71.2$) than did those in the low-ability condition ($M = 53.7$), $F(1, 77) = 17.19$, $p < .001$, $MS_e = 807.4$, $d = .945$. And subjects in the high-ability condition also gave higher ratings of their pupils' intellectual potential ($M = 89.1$) than did those in the low-ability condition ($M = 77.1$), $F(1, 82) = 10.29$, $p = .002$, $MS_e = 671.9$, $d = .708$.

Subjects' hypotheses regarding study. When asked for their hypotheses regarding the purposes of the study, nearly one half (44) of the subjects named a theme related in some way to the teacher expectancy idea (e.g., suggesting that the study's purpose was to assess the impact of pupil background on teaching style). Most of the remaining group repeated the cover story told them by the experimenter, or named an unrelated hypothesis. (As will be reported subsequently, where effects of ability on teaching behavior were found, these were confirmed in analyses that excluded the 44 subjects holding accurate suspicions about the research purpose.) Only eight subjects revealed skepticism about the existence

---

[3] Subject behavior after correct "pupil" responses was coded into three all-inclusive categories—praise feedback, correctness feedback (without praise), and feedback omitted. Thus the incidence of praise and feedback omission measures reported here represent all nonredundant information about type of feedback behavior following correct "pupil" responses. Subject behavior after incorrect "pupil" responses was, with a few exceptions (e.g., cases in which subjects enthusiastically confirmed the correctness of incorrect answers), coded into two categories—incorrectness feedback given or omitted. Thus, virtually all nonredundant information about type of feedback behavior following incorrect responses is represented in the feedback omission variable.

[4] Accidentally giving away question responses was not the only type of inadvertent behavior evidenced by the subjects. Two subjects in the black-pupil condition talked to their pupils about the "watermelon" as they looked at a question card containing both a large picture of an apple and a boldface caption referring to the "apple."

Table 1
Summary of Analysis of Variance Effects

Effect	Measure category	Measure	p
Ability (A)	Input	Teaching pace	.022
	Output	Impatience	.028
	Feedback	Praise feedback length	.009
	Vocal anxiety	Speech errors	.033
		Vocal nervousness	.075
Race (B)	Feedback	Positive feedback omission	.056
		Incorrectness feedback length	.054
	Freudian helpfulness	Helpful slips	.017
Sex (C)	Climate	Head nodding	.026
B × C	Feedback	Positive feedback omission	.049
	Freudian helpfulness	Helpful slips	.009
B × Awareness × Time	Output	Impatience	.065
	Feedback	Positive feedback omission	.019
B × A	Climate	Vocal warmth	.023
		Forward leaning	.031
	Freudian helpfulness	Helpful slips	.026
C × A	Feedback	Praise feedback incidence	.009
	Freudian helpfulness	Helpful slips	.026

Note. Relevant Fs and effect size estimates are presented in the text. Subgroup means for main effects are presented in the text, those for interaction effects in Tables 2–5.

of an actual child in the observation room, and many of the subjects responded in a way that confirmed their belief in the existence of an actual pupil, for example, by showing concern for the reactions of a child to the experimental procedure or by suggesting that pupil learning was the dependent variable of interest.

Reliabilities and intercorrelations. Reliabilities of the kinesic ratings were estimated using the independent ratings of a second rater for a subsample of the subjects. For smiling, $r(11) = .577$ and $r(29) = .830$ for the first and second lesson presentations, respectively; for head nodding, $r(12) = .703$ and $r(29) = .850$ for the first and second lesson presentations; and for leaning forward, $r(13) = .863$ and $r(20) = .715$ for the first and second lessons.

Since neither rater race nor timing of excerpt interacted appreciably with experimental condition in affecting voice ratings, analyses were performed on the means of the 16 ratings available for each subject from each lesson presentation. Reliabilities were computed from mean squares by a procedure that yields estimates equivalent to those produced by applying the Spearman-Brown prophecy formula to the mean interrater correlation. (See Guilford, 1954, p. 395.) For the cold–warm dimension, $r(94) = .673$ and $r(92) = .780$ for the first and second lesson presentations, respectively; for the nervous–calm dimension, $r(92) = .735$ and $r(90) = .767$ for the first and second lesson presentations. The correlation between ratings on these two dimensions was $r(98) = .394$ for the first lesson presentation and $r(98) = .502$ for the second lesson presentation.

To assess reliability of the feedback measures, a second set of feedback data was coded from the audiotape for a subsample of subjects giving their first lesson presentation. For the praise incidence measure, $r(35) = .946$; for praise feedback length, $r(35) = .949$; for incorrectness feedback length, $r(28) = .322$; for positive feedback omission, $r(33) = .856$; for negative feedback omission, $r(33) = .450$.[1]

Correlations among feedback measures showed that indeed these indicators are minimally redundant. There is essentially no relation between rates of omission of positive and negative feedback, and relations between feedback incidence and feedback length are weak and inconsistent in direction.

[1] The modest reliability coefficients on the two feedback omission measures reflect the fact that the subjects' verbalizations were often ambiguous, leaving interpretation dependent on the subtleties of vocal inflection. The low incorrectness-feedback-length coefficient reflects the relative rarity of incorrect "pupil" responses, along with the subjects' tendency to follow such responses with lengthy statements in which the line between feedback and exposition was unclear.

Results

An overview of the analysis of variance effects to be reported and discussed is presented in Table 1.

Behavioral Mediators of Ability-Expectancy Effects

Main effects of pupil ability in the expected direction were shown on central indicators of two of the four categories of mediators suggested by Rosenthal (1973)—the input and output factors. Subject teachers in the low-ability condition taught at a slower pace and thus presented less material to their pupils in the alloted time ($M = 103.3$) than did those in the high-ability condition ($M = 115.7$), $F(1, 84) = 5.45$, $p = .022$, $MS_e = 1{,}377.1$, $d = .509$.[6] Perhaps more interestingly, subjects in the low-ability condition were less patient in waiting for responses to questions, interrupting the latency period between question and response ($M = .39$) more frequently than subjects in the high-ability condition ($M = .23$), $F(1, 83) = 5.06$, $p = .028$, $MS_e = 2{,}400.8$, $d = .494$.

Among the several feedback indicators, there were main effects of pupil ability on only one: Statements praising pupils after correct responses were more lengthy among subjects in the low-ability condition ($M = 2.87$) than among those in the high-ability condition ($M = 2.03$), $F(1, 78) = 7.24$, $p = .009$, $MS_e = 447.1$, $d = .609$. The null results on the feedback incidence measures represent a failure to confirm Rosenthal's (1973) suggestion that high-ability pupils receive clearer and more consistent feedback from teachers,[7] but the significant effects on feedback length do not represent a reversal of his prediction: Average length of positive feedback was not an aspect of teacher behavior discussed by Rosenthal or assessed in the studies he reviewed, and intercorrelations among measures in the present study showed feedback length to be unrelated to those incidence measures Rosenthal did discuss.

Rosenthal's fourth factor, climate, was the one category that showed no significant main effects of pupil ability, although, as will be reported later, there was a highly interesting Race × Ability interaction on a primary climate indicator, vocal warmth.

The effects of the ability manipulation on the measures of vocal anxiety suggest a category of expectancy mediator that Rosenthal did not discuss. Low-ability subjects made fewer speech errors ($M = 3.15$) than did high-ability subjects ($M = 4.14$), $F(1, 84) = 4.72$, $p = .033$, $MS_e = 10.05$, $d = .474$. And there was a nearly significant effect of pupil ability on rated vocal nervousness, the content-filtered speech of subjects in the low-ability condition being rated as less nervous ($M = 5.36$) than that of those in the high-ability condition ($M = 5.08$), $F(1, 84) = 3.25$, $p = .075$, $MS_e = 12{,}018$, $d = .393$.[8]

In summary, these data support Rosenthal's hypothesis that low-ability pupils are taught less and are given fewer response opportunities than are high-ability pupils. The low-ability group did not give less clear or consistent feedback in the present study; praise given after correct responses was more extensive in this group than among the high-ability subjects. And the climate provided by the low-ability group as a whole was not less warm than that provided by the high-ability group. Vocal anxiety is suggested by these results to be an additional category of teacher

---

[6] All analysis of variance results reported are from repeated measures analyses with four between-subjects factors (pupil ability, pupil race, pupil sex, and awareness) and one within-subjects factor (Time, i.e., first vs. second lesson presentation).

Throughout the article $d = 2\sqrt{F \div df}$ for error term. Thus any given between-groups difference is standardized by the within-cell standard deviation estimated from the sums of squares of the error term of the corresponding F. Conventionally, $d = .20$ is considered a small effect, $d = .50$ a medium effect size, and $d = .80$ large (Cohen, 1969, p. 38). Minor fluctuations in degrees of freedom for these analyses reflect occasional missing data.

[7] The feedback-omission indicators are the most relevant to Rosenthal's hypothesis, and the modest reliabilities of these measures suggest one possible explanation for the absence of the predicted ability effects.

[8] One reader suggested that the indications of anxiety among subjects in the high-ability condition might be tied to the relatively rapid teaching pace of this group. Intercorrelations show, however, that there was no substantial relation between teaching pace and either speech errors or vocal nervousness.

expectancy mediator; the subjects teaching low-ability pupils manifested less nervousness.[9]

Pupil-Race Effects

The subjects' ratings of their pupils, mentioned earlier as a means of assessing the potency of the ability manipulation, revealed those in the black-pupil condition to profess superior performance expectations of their pupils. Subjects who believed their pupils were black indicated in their ratings that they expected the lesson to be easier for their pupils ($M = 67.4$) than did those in the white-pupil condition ($M = 57.6$), $F(1, 77) = 5.38$, $p = .023$, $MS_e = 807.4$, $d = .529$.

However, the teacher *behaviors* that are the dependent variables of the present study did not reveal a pattern of particularly favorable treatment directed at black pupils. (The only effect plausibly interpretable as favorable to blacks is a trend for those with black "pupils" to give briefer feedback after incorrect responses ($M = 2.94$) than those with white "pupils" ($M = 4.65$), $F(1, 42) = 3.94$, $p = .054$, $ME_e = 2{,}026.2$, $d = .613$. The two other main effects of pupil race on teaching behavior suggest negative teacher orientation toward black students, if anything. Omission of positive feedback after correct responses was more frequent in the black-pupil condition ($M = 5.49$) than in the white-pupil condition ($M = 2.45$), $F(1, 84) = 3.76$, $p = .056$, $MS_e = 119.7$, $d = .423$. And subjects with black "pupils" were less likely to make helpful slips of the tongue that gave away answers ($M = .04$) than were those with white "pupils" ($M = .15$), $F(1, 84) = 6.04$, $p = .017$, $MS_e = .084$, $d = .536$.[10] These effects should be interpreted, however, in conjunction with the Race × Sex interaction on these two measures.

The Interactive Effects of Pupil Race and Sex

Pupil race and sex were found to interact in affecting both positive feedback omission and helpful slips. Relevant cell means are presented in Table 2. The subjects in the black-male and white-female groups were less likely to offer their pupils either kind of assistance—positive feedback after correct responses, $F(1, 84) = 4.00$, $p = .049$, $MS_e = 119.7$, $d = .436$, or helpful slips while asking questions, $F(1, 84) = 7.30$, $p = .009$, $MS_e = .084$, $d = .590$[11]—than were the subjects in the white-male and black-female groups. The combined impact of these interaction effects and the main effects of pupil race on these two variables is evident in Table 2.

Table 2
Race × Sex Interactions

Pupil race	Pupil sex: Male	Pupil sex: Female
Positive feedback omission[a]		
Black	7.78	3.19
White	1.61	3.29
Helpful slips[b]		
Black	.02	.07
White	.24	.06

[a] Scores summarized by these cell means are percentages of correct pupil responses that met with no teacher feedback. The actual range of scores is from 0 to 70.

[b] Scores summarized by these cell means represent total number of times a subject made an apparent slip of the tongue and gave away the answer while trying to ask a question. The range of scores is from 0 to 2.

[9] As mentioned earlier, 44 subjects reported suspicions that the purpose of the study was to investigate effects of pupil background on teacher behavior. Supplementary analyses showed that the ability effects reported here were more pronounced among the naive subjects than in this suspicious group for all except one dependent measure, praise feedback length. On the praise-feedback-length indicator, the ability effect within the naive group was large enough to have been significant had the entire group of subjects remained naive. Apparently, then, the ability effects reported above are not artifacts created by cooperative subjects.

[10] The helpful slips measure is badly skewed, since only 17 of the 100 subjects made any such slips, so the probability associated with the F should be accepted with caution. To confirm the conclusion that the effect was significant, the likelihood of the observed distribution of those 17 cases between pupil-race conditions was assessed using chi-square. For this effect $\chi^2(1) = 7.56$, $p < .01$.

[11] For this effect, $\chi^2(1) = 5.74$, $p < .025$. (See explanation in Footnote 10.)

Table 3
Race × Awareness × Time Interactions

Group	Time 1	Time 2
Positive feedback omission[a]		
Black		
Aware	11.1	5.4
Unaware	3.4	2.0
White		
Aware	1.2	1.7
Unaware	6.8	.0
Impatience[b]		
Black		
Aware	.37	.32
Unaware	.31	.34
White		
Aware	.24	.32
Unaware	.32	.28

[a] Scores summarized by these cell means are percentages of correct pupil responses that met with no teacher feedback. The actual range of scores is from 0 to 70.

[b] Scores summarized by these cell means represent average number of times, per question asked, that subjects interrupted the latency period between question and response called for by the response schedule. The range of scores is from 0 to 1.8.

Positive feedback is most often withheld in the black-male group, most often given in the white-male group; and helpful slips are least frequent in the black-male group, most frequent in the white-male group.

The Awareness Manipulation Test for Repression of Affect

The repression-of-affect idea was directly tested here via the awareness manipulation, and it is the three-way interactions involving pupil race, awareness, and time that announce the verdict. Support for the repression-of-affect notion would be provided by a pattern of such interaction effects showing controllable, positive behaviors to increase disproportionately among subjects in the aware – black-pupil condition after the awareness manipulation was given, and uncontrollable negative behaviors similarly to increase among this group. Cell means relevant to the two significant or nearly significant Race × Awareness × Time interactions are presented in Table 3. It can be seen that the awareness manipulation encouraged the decrease of positive feedback omission among those with black "pupils," while depressing such a decrease among those with white "pupils," $F(1, 84) = 5.74$, $p = .019$, $MS_e = 70.5$, $d = .523$. And there was a nearly significant tendency for the awareness manipulation to discourage impatience in subjects in the black-pupil condition but encourage impatience in subjects in the white-pupil condition, $F(1, 83) = 3.51$, $p = .065$, $MS_e = 319.8$, $d = .411$.

These effects suggest that the awareness manipulation may have produced the intended demand characteristics: The manipulation may have increased, for black-pupil-condition subjects relative to white-pupil-condition subjects, the incidence of behaviors widely assumed to represent good teaching practice. However, there is no evidence that the relative advantages that may have been conferred on black pupils by the awareness manipulation were accompanied by disproportionate increases in uncontrollable disadvantageous teaching behaviors. And there are difficulties even in the interpretation of the two effects that did occur: The pattern of means does not suggest that certain demand characteristics were produced uniquely in the aware – black-pupil condition; and premanipulation (Time 1) differences between aware and unaware groups throw doubt on any conclusions about the manipulation's effect. All in all, it must be said that we fail to find any support for the repression-of-affect idea in these data.[12]

[12] It was in the pattern of correlations among measures that Weitz (1972) found evidence for the repression-of-affect proposition. The correlations among measures for the various Race × Awareness subgroups after the awareness manipulation had been implemented were examined here as well. The repression-of-affect prediction would be the following: for some pairs of behaviors, one member controllable and the other not, there would be a correlation in one direction in the white-pupil group, reflecting affective congruence of the two behaviors; for the unaware-black group there would be a weaker correlation, or a correlation in the opposite direction, reflecting the combination of dissembling and leak-

The Interactive Effects of Pupil Race and Ability

It is the interactive effects of pupil race and ability that are probably the most intriguing results of the present study. Cell means relevant to the three such interactive effects that reached or approached significance are presented in Table 4. Relative to those in the other two Race × Ability cells, subjects who believed they were teaching high-ability – black and low-ability – white pupils spoke in warmer tones, $F(1, 84) = 5.39$, $p = .023$, $MS_e = 16{,}227.6$, $d = .507$. Additionally, those in the high-ability – black and low-ability – white pupil groups were more likely to make helpful slips as they asked questions, $F(1, 84) = 5.19$, $p = .026$, $MS_e = .084$, $d = .497$.[13] And, there was a nearly significant tendency for these groups to lean forward less often as they addressed their pupil, $F(1, 82) = 3.95$, $p = .051$, $MS_e = 8{,}666.1$, $d = .439$.[14]

The direction of the Race × Ability effect on forward leaning is puzzling in light of the

Table 4
Race × Ability Interactions

Pupil race	Pupil ability: High	Pupil ability: Low
	Vocal warmth[a]	
Black	5.29	4.80
White	4.84	5.20
	Helpful slips[b]	
Black	.09	.00
White	.09	.16
	Forward leaning[c]	
Black	121.8	148.4
White	134.9	108.1

[a] Scores summarized by these cell means are means of 16 rater judgments of content-filtered excerpts on a 9-point cold–warm scale, where warm is high. The range of scores is from 2.31 to 7.50.
[b] Scores summarized by these cell means represent total number of times a subject made an apparent slip of the tongue and gave away the answer while trying to ask a question. The range of scores is from 0 to 2.
[c] Scores summarized by these cell means represent seconds of leaning toward the observation room window during three 1-min periods of a lesson presentation. The actual range of scores is from 0 to 180.

age; and for the aware-black group, subject to still stronger demand characteristics, there would be even greater deviation from the white-condition relationship. Pairs of measures were judged to represent this pattern if the correlations of the aware-white and unaware-white groups were not significantly different from each other, if the aware-black group was significantly different from the white group, and if the correlation of the unaware-black group was intermediate and not significantly different from the pooled correlations of the aware – black-pupil and aware – white-pupil conditions.

Requirements for this pattern were technically met by three pairs of variables in the present study, but none of the three cases provides clear support of the Weitz repression and leakage idea. The correlation between speech errors and persistence was negative in the white condition, $r(50) = -.275$, weak and positive in the unaware-black group, $r(19) = .184$, and positive and slightly stronger in the black-aware group, $r(25) = .278$. However, it is not clear that persistence and speech errors have contradictory affective implications. Persistence and head nodding were the second pair of measures that met the pattern: The correlation between them was weak and positive, $r(49) = .157$, in the white-pupil condition, near zero, $r(19) = .005$, in the black-unaware condition, and moderate and negative, $r(25) = -.422$, in the aware-black condition. The third pair was head nodding and positive feedback omission: The correlation was near zero, $r(24) = .022$, in the white-pupil condition, weak and positive, $r(19) = .116$, in the unaware-black condition, and moderate and positive, $r(25) = .440$, in the aware-black condition. In the case of the second and third pairs, it is possible to interpret the pattern of behavior typical of the aware-black group as affectively incongruent—head nodding being associated with lack of persistence in the first case and with omission of positive feedback in the second. However, for both of these pairs of variables, the differences between the correlations for the white and the unaware-black groups were trivial. And the Weitz discussion suggests that evidence of the dissembling and leakage phenomenon should be detectable even in the absence of conditions such as the awareness manipulation in the present study, which may heighten it.

In short, evidence from subgroup correlations offers no stronger support for the repression-of-affect idea than did interactive effects of pupil race, awareness, and time.

[13] $\chi^2(1) = 3.48$, $p < .10$. (See explanation in Footnote 10.)

[14] Supplementary analyses (see Footnote 9) showed these effects to be stronger for naive subjects than for suspicious subjects, except in the case of the helpful-slips measure.

Table 5
Sex × Ability Interactions

Pupil ability	Pupil sex: Male	Pupil sex: Female
Praise feedback incidence[a]		
High	67.3	58.3
Low	56.5	74.2
Helpful slips[b]		
High	.08	.11
Low	.17	.02

[a] Scores summarized by these cell means are percentages of correct responses followed by explicit praise. The actual range is from 0 to 100.
[b] Scores summarized by these cell means represent total number of times a subject made an apparent slip of the tongue and gave away the answer while trying to ask a question. The range of scores is from 0 to 2.

vocal-warmth and helpful-slips effects. It appears that leaning should not be assumed to serve as an alternate indicator of warmth. The negative correlations between the two measures, $r(93) = -.144$, $p < .10$, for the first lesson presentation, and $r(91) = -.249$, $p < .05$, for the second lesson presentation, support this conclusion. Future investigation of the correlates of leaning behavior seems in order. In the meantime, we can note that the more direct and interpretable indicator of climate, vocal warmth, along with inadvertent helpfulness, was mostly likely to exist among those in the high-ability – black and low-ability – white conditions. This finding seems to contradict the Rubovits and Maehr (1973) conclusion that high-ability – black and low-ability – white groups are the recipients of the most detrimental teacher behaviors.

Pupil Sex Effects and the Interactive Effects of Sex and Ability

Main effects of pupil sex are negligible. The only behavior showing a significant effect of pupil sex was head nodding, girls receiving more frequent up-and-down head nods ($M = 2.66$) than boys ($M = 1.62$), $F(1, 82) = 5.19$, $p = .026$, $MS_e = 10.1$, $d = .503$. And even this effect is difficult to interpret. Head nodding had been assumed to be an indicator of climate or warmth, but that assumption is thrown into serious question by the fact that head nodding did not show substantial correlations with any of the other kinesic measures or with ratings of vocal warmth. We thus must say that there were no readily interpretable effects of pupil sex on teacher behavior. This finding is congruent with the conclusions of Brophy and Good (1974) that such pupil-sex effects on teacher behavior as do exist in classroom situations are the product of actual behavior differences among male and female pupils.

Interactive effects of pupil sex and ability, like main effects of pupil sex, are neither numerous nor readily interpretable. Relevant cell means are presented in Table 5. On the one hand, the high-ability – female and low-ability – male groups revealed a lower incidence of praise feedback than did the other two Sex × Ability groups, $F(1, 84) = 7.25$, $p = .009$, $MS_e = 1{,}194.4$, $d = .588$.[15] However, it was also subjects in the high-ability – female and low-ability – male groups who were most likely to make helpful slips of the tongue, $F(1, 84) = 5.19$, $p = .026$, $MS_e = .084$, $d = .497$.[16] Thus, we see the least intentional encouragement, in the form of praise after correct responses, being directed to those groups that receive the greatest unintentional assistance in the form of helpful slips.

Discussion

The Mediation of Teacher Expectancy Effects

The present findings provide strong support for Rosenthal's (1973) conclusion that two of the modes in which teachers may adapt their behavior to reflect differential expectations of their students are by adjusting the

[15] Supplementary analyses (see Footnote 9) showed the effect on helpful slips to be stronger among naive subjects than among suspicious subjects. The interaction effect on praise feedback incidence is slightly stronger for suspicious subjects than for naive subjects, but the effect within the naive group was large enough to have been significant had the entire group of subjects remained naive.

[16] $\chi^2(1) = 3.48$, $p < .10$. (See explanation in Footnote 10.)

pace of their teaching and by varying the response opportunities allowed the children.

The pattern of feedback behavior noted here merits more detailed comment. First, the virtual independence of the various measures of teacher feedback suggests that it is not appropriate simply to speak of feedback as being more or less good, or strong, or clear. Differentiated questions must be asked about rates of teacher feedback, quality of feedback, and extensiveness of feedback. The finding that subjects in the low-ability condition offered longer statements of praise than did those in the high-ability condition was unexpected; however, several plausible interpretations suggest themselves. There may have been a contrast effect at work, a tendency for subjects to express surprise at the accomplishment of low-ability pupils by giving elaborate praise. Or, the subjects may have been taught self-consciously to use praise as a shaping technique, and perhaps were most diligent in the application of this technique when addressing a low-ability pupil. Alternately, focusing on the relative brevity of praise feedback given in the high-ability group, perhaps subjects who believed their pupils to be bright functioned under pressure of demand characteristics dictating that the measure of their teaching ability was the amount of material covered; cutting short the positive verbal feedback was one way of speeding things up. (Correlations between teaching pace and length of praise feedback are negative and moderately strong.)

Similarly, it is not difficult to find plausible explanations for the pupil-ability effect on vocal nervousness. Teachers may see low-ability pupils as less threatening than high-ability pupils, and thus may approach them with less anxiety.

The absence of pupil-ability effects paralleling those found on climate indicators in prior research remains unexplained. Perhaps climate was the aspect of teacher behavior least amenable to natural expression in the absence of actual face-to-face interaction. The results here do suggest that the various kinesic and paralinguistic measures assumed to represent climate do not necessarily correlate strongly or even positively with each other, and therefore should not be assumed to be indicators of the same construct.

It must be remembered that only half of the mediation question was addressed in the present study. We have examined effects of pupil ability on teacher behavior, but behaviors spotlighted as mediators of teacher expectancy effects must have their impact on student performance, as well as show an impact of pupil-ability label. The teacher behaviors that showed pupil-ability effects here probably vary in their influence on pupil performance. In actual classroom situations, it may often be sound pedagogical practice to adjust lesson pacing in accordance with pupil ability. Thus, the effect of pupil-ability label on teaching pace may only be a problem where ability assessments are faulty. In contrast, the observed tendency to give children with low-ability labels less time to answer questions must clearly be dysfunctional for those children, the more so because the correlational analysis showed interruptions of the latency period between question and response often to take the form of additional questions, requiring different responses. Bombardment with a series of follow-up questions, before the pupil has had the chance to respond to the original question, would make successful performance difficult for any child; for the child who may indeed already have learning problems, such teacher behavior may present an insurmountable obstacle to successful performance. Length of praise feedback and vocal nervousness fall into still a third category, showing effects of pupil-ability label but not having prima facie positive or negative implications for pupil performance.

Clearly, the results of numerous field and lab studies, examining effects of teacher behaviors as well as their causes, must be accumulated before we can be satisfied with our understanding of the mediation of teacher expectancy effects.

The Joint Effects of Pupil Race and Sex

The effects of pupil race on teacher behavior in the present study were limited. There does seem to be a tendency for black "pupils" to be recipients of the less positive teacher behaviors. Perhaps more interesting, however, is

the observation that on the two indicators that appeared to show a bias against black pupils —the positive-feedback-omission and helpful-slips variables—there were also Race × Sex interactions, the two effects together implying that white male students receive the most favorable treatment, black male students, the most unfavorable. The parallel between this result and recent Census Bureau statistics is noteworthy: In 1974, educational attainment was highest among white males, lowest among black males (with white and black females intermediate) (Farley, 1977).

The Repressed-Affect Model

It is encouraging that the awareness manipulation, designed to evoke conscious efforts at problack behavior, did not also create detectable leakage of negative affect. The explanation for the incongruence of the present results and those of Weitz (1972) remains to be ascertained.

The Null Results of the Pupil-Sex Manipulation

It is the lack of a pronounced pattern of pupil-sex or Sex × Ability effects that is interesting here. Perhaps Brophy and Good (1974) are correct in suggesting that classroom teachers merely respond to behavioral differences in male and female pupils, differences that originate elsewhere. Other possibilities merit exploration, however. Certain kinds of pressure for sex role specialization intensify as children enter adolescence. It may be the case that differential teacher treatment of male and female pupils is pronounced, but for children older than the phantom 6-year-old of this study. It may also be the case that effects of pupil sex do exist, even among teachers of young children, but on dimensions of behavior different from those selected for attention in the present study. For example, Dweck (1976) discusses the differential rates of praise and criticism teachers direct at male and female children for nonintellectual aspects of their performance. Dweck believes that experience with nonspecific feedback affects pupil sensitivity to positive and negative feedback on intellectual tasks, and that the sex difference in receipt of nonspecific feedbac creates a sex difference in response to fail ure. This potentially important dimension o teacher behavior, nonspecific feedback, is on of those that obviously could not be represente here, since our teacher subjects had the op portunity to give feedback specific only t intellectual tasks.

The Race by Ability Interaction Effect o Vocal Warmth

One of the most interesting observations o the present study is that pupil race and ability interacted to influence teacher affective orientation in a direction favoring high-ability – black and low-ability – white pupil groups. As noted earlier, this effect is opposite in direction from that found by Rubovits and Maehr (1973). Why might teachers be positively disposed toward high-ability – black and low-ability – white pupils? Findings of Datta et al. (1968) suggest an explanation.

When Datta et al. asked a predominantly white group of seventh-grade teachers to rate selected black and white pupils in their classes on a variety of dimensions, the high-ability – black and low-ability – white groups were rated higher on positive task orientation and lower on verbal aggression than were low-ability blacks and high-ability whites.

Intuition suggests that most teachers would prefer pupils to manifest the orderly and submissive patterns of behavior represented by high task orientation and low verbal aggressiveness, and in this case there is ample empirical evidence to support the intuitive conclusion. Feshbach (1971) finds, for example, that teachers most prefer rigid, conforming, and orderly pupil descriptions, and least prefer those that are independent, active, and assertive. The interaction effect noted in the present study may, then, reflect teacher anticipation that high-ability blacks and low-ability whites will be relatively trouble-free students, and low-ability blacks and high-ability whites relatively troublesome.

External Validity and the Need for Naturalistic Research

The limitations of this phantom pupil design must be acknowledged. In the present

study we tried to simulate one-to-one interaction instead of the typical group teaching situation, and for one of the interactants we depended on our cover story's credibility, the subjects' imaginations, and a remote-control light panel. The reader is invited to be as concerned about the external validity of the study as we are. On the other hand, as in virtually all social psychology research, we necessarily had to accept some limitations in order to avoid others. A great deal of research has been done in more naturalistic settings where, typically, the lack of control precluded some behavioral measures and meant that extraneous pupil characteristics were possibly confounded with those of primary interest. In order to employ the range of refined measures represented here, and to be assured that we could look at clean effects of pupil race, sex, and ability, a design was selected that leaves open some questions about generalizability. If we are to reap maximum value from this study's strengths and minimize the ramifications of its potential weaknesses, the present results must be considered along with evidence from more naturalistic classroom studies.

Concluding Comments

Directions that could profitably be taken in future research are undoubtedly obvious to the reader. There is the need for further data to be gathered in actual classrooms and in controlled laboratory settings, focusing on black teachers and males, as well as on white female teachers. Conceptualization and empirical work relevant to the dimensionality of teacher behavior will provide valuable additions to existing understandings. And, if we are to talk of the impact that various teacher orientations may have on pupil performance, there needs to be much more extensive evidence collected concerning the effect of teacher behaviors on pupils.

Attitude Organization and the Attitude–Behavior Relationship

Richard P. Bagozzi and Robert E. Burnkrant
University of California, Berkeley

The validity of a single-component model of attitude was assessed and compared with a two-component (affective/cognitive) conceptualization of attitude. Confirmatory factor analysis was employed in a reanalysis of data previously reported by Fishbein and Ajzen in the *Psychological Review*. Convergent validity, in the sense of uniform consistency of responses, was found not to hold for the single-component model but was achieved for the two-component model. Further, the two-component model of attitude was found to predict scaled, but not unscaled, multiple-act behavior criteria; and the predictive validity of the relationship between the two-component model and single-act behavior criteria was not supported.

Considerable research attention has been directed at the attitude–behavior relationship. Much of this research has yielded disappointingly weak results (e.g., Berg, 1966; Bray, 1950; Kutner, Wilkins, & Yarrow, 1952; La Piere, 1934; Nemeth, 1970). Wicker (1969) reviewed over 30 studies concerned with the attitude–behavior relationship and concluded that in most cases attitude is either unrelated or only slightly related to behavior.

The failure to find consistent, strong relationships between attitude and behavior has led to elaboration and clarification of the attitude construct and to further specification of its relationship to behavior. It is frequently argued that attitude is a multidimensional construct and that simultaneous consideration of these several dimensions will provide better predictions of behavior than the consideration of a single attitudinal dimension or component alone (Krech, Crutchfield, & Ballachey, 1962; Norman, 1975). Other researchers argue that attitude may be appropriately regarded as a single dimension of affect and that the relationship between attitude and behavior would be stronger if both attitudinal predictors and behavioral criteria were measured at an equivalent level of generality (e.g., Fishbein, 1967b; Fishbein & Ajzen, 1975). Fishbein and his associates maintain that a general attitude should be predictive of a general set of behaviors, but it should bear no necessary relationship to any specific behavior the researcher might be interested in (Ajzen & Fishbein, 1977; Fishbein, 1973; Fishbein & Ajzen, 1974).[1]

This article addresses both of these issues. In doing so, it provides empirical tests of the validity of the multicomponent and single-component models of attitude. Second, it tests the validity of the relationship between a general attitude and single-act criteria and between a general attitude and multiple-act criteria. Finally, it examines the relationship between attitude and scaled measures of behavior.

The ordering of the authors' names is alphabetical; both authors contributed equally to the research.

Robert E. Burnkrant is now at the Ohio State University.

Requests for reprints should be sent to Richard P. Bagozzi, who is now at the Alfred P. Sloan School of Management, Massachusetts Institute of Technology, 50 Memorial Drive, Cambridge, Massachusetts, 02139.

[1] Many other factors have been cited to explain the lack of consistently strong positive relationships between attitude and behavior. These will be treated in the discussion section of this article, but for a fuller treatment see Calder and Ross (1973), Fishbein and Ajzen (1975), Kelman (1974), and Wicker (1969).

Attitude Organization

Those who hold a multidimensional view of attitude consider it to be a complex construct comprised of an affective (i.e., feeling) component, a cognitive (i.e., knowledge) component, and a conative (i.e., behavioral) component (Krech et al., 1962; Smith, 1947). Rosenberg and Hovland (1960) regard attitude as a predisposition to respond to some class of stimuli with cognitive, affective, and behavioral responses. They suggest that each response class is mediated by a separate component of attitude. Greenwald (1968) maintains that these components may have separate antecedents. He further suggests that affect may be formed through classical conditioning, cognitions through cognitive learning, and conations through instrumental learning or operant conditioning.

It has been pointed out, in accordance with a multicomponent view of attitude, that people may hold the same attitude as measured by one index of attitude and yet hold very different attitudes in terms of their standing on the other unmeasured components (e.g., Rosenberg & Hovland, 1960). It is implied that the attitude–behavior relationship will be stronger when the components are consistent than when they are inconsistent (e.g., Rosenberg, 1968; Rosenberg & Hovland, 1960). Failure to find a consistent, direct relationship between attitude and behavior may be due, then, to failure to measure people's standing on all three components of attitude and employ these as simultaneous predictors of behavior. The three-component view suggests that cognitive, affective, and conative evaluations of objects are distinguishable aspects of attitude and that simultaneous consideration of all three components should be most predictive of overt behavior.

The major alternative to the three-component view treats attitude as a single dimension of affect for or against an object. In accordance with this position, Fishbein (1967b) points out that although definitions of attitude usually refer to three components, it is the evaluative or affective component that is usually measured and treated as attitude. He argues that all attitude-scaling techniques have in common the characteristic that they place individuals on a dimension of affect for or against a psychological object. According to this view, alternative approaches to the measurement of attitude provide alternative measures of the same thing (i.e., affect) and should yield the same results. Obtained differences among alternative attitude instruments would be due, therefore, to measurement error and not the assessment of valid alternative components.

A third and intermediate position is maintained in the present article. Attitude is considered to be a complex construct comprised of cognitive and affective components. These components are believed to simultaneously account for behavioral intentions or actual behavior.[2]

Katz and Stotland (1959) and Rosenberg (1968) assert that all true attitudes must have both cognitive and affective content although they need not include a conative component. Rosenberg (1968) notes that with the exception of cognitive dissonance,

> The authors and proponents of most of the other consistency theories pay ready lip service to the definition of attitude as an internally consistent structure of affective, cognitive and behavioral components. But, in practice, the last of these components is usually slighted. Behavior (in the sense of externally visible, overt action) toward the attitude object is usually relegated to the status of a dependent variable; implicitly it is assumed that the person will simply act toward an attitude object in a manner consistent with his coordinated affective–cognitive orientation toward that object. (p. 101)

The two-component attitude position taken here recognizes and is consistent with the fact that self-reported behavior and stated intentions to respond have frequently been treated as dependent effects of affective and/or cognitive variables (e.g., DeFleur & Westie, 1958; Linn, 1965; Nemeth, 1970; Rogers & Thistlethwaite, 1970; Sample & Warland, 1973; Tittle & Hill, 1967). Intentions seem to be at a

[2] It is also recognized that behavior may lead to changes in the affective and cognitive components of attitude as a result of learning and self-perception or dissonance effects. However, explicit consideration of these feedback effects is beyond the scope of this research.

lower level of abstraction (i.e., closer to observable behavior) than cognitions or affect.

Several attemps have been made to provide empirical support for a multicomponent conceptualization of attitude. The results of these studies have been equivocal at best. Woodmansee and Cook (1967) factor analyzed scales designed to measure attitude toward blacks. They failed to obtain unique factors that could be interpreted as representing cognitive, affective, and conative components of attitude. Based on judgment procedures, Ostrom (1969) and Kothandapani (1971) developed Guttman, Likert, Thurstone, and Guilford self-rating attitude scales for each component of attitude. People then responded to cognitive, affective, and conative scales. Using Campbell and Fiske's (1959) multitrait–multimethod matrix approach and criteria, both researchers concluded that obtained correlations among the attitude component scores provided evidence for convergent and discriminant validity for the affective, cognitive, and conative components. However, in a reanalysis of both data sets, Bagozzi (1978) found that discriminant validity was obtained for the Ostrom, but not the Kothandapani, data. Thus, only the Ostrom study provides clear support for a multicomponent attitude model.

An objective of the present article is to provide empirical tests of the validity of the two-component and single-component models of attitude. This research involves a reanalysis of data presented by Fishbein and Ajzen (1974). In that study, each subject's attitude toward "being religious" was assessed on Thurstone, Guttman, Likert, semantic differential, and Guilford self-rating scales. In addition, subjects provided responses to either 100 behavioral intention items or 100 self-reported behaviors. While the approach taken by Fishbein and Ajzen was consistent with a unidimensional approach to attitude in that all five attitude scales were treated as alternative measures of attitude, it is our contention that the evaluative dimension of the semantic differential and the Guilford self-rating scale represent alternative measures of the affective component of attitude and that the Guttman, Likert, and Thurstone scales represent alternative measures of the cognitive component of attitude.

Theory and research tend to support this distinction. Katz and Stotland (1959) identified the affective component with attributions of good or bad qualities. Osgood, Suci, and Tannenbaum (1957) defined attitude as the projection of a concept on the evaluative dimension of semantic space. Similarly, various other researchers have presented arguments and evidence for using the evaluative dimension of semantic space as a measure of affect (cf. Davidson & Jaccard, 1975; Fishbein & Raven, 1962; McGuire, 1969; Norman, 1975). In a parallel fashion, the Guilford self-rating favorable/unfavorable scale can be used to measure affect. Conceptual and empirical support for this claim can be found in Ostrom (1969), Kothandapani (1971), and Norman (1975).

The affective component measures the degree of emotional attraction toward an attitude object. The cognitive component, in contrast, accounts for the perceived relationship between attitude object and other objects or concepts. The cognitive component typically covers "beliefs about the object, characteristics of the object, and relationships of the object with other objects" (Ostrom, 1969, p. 16). With regard to the specific cognitions employed in the present research, Fishbein and Ajzen (1974) maintain that "the other three attitude measures [i.e., the Guttman, Likert, and Thurstone scale] were standard religiosity scales based on opinion items" (p. 62). Elsewhere, Fishbein and Ajzen (1975, p. 12) consider opinions to be cognitions, and they distinguish them from affect and conation. In their study, Fishbein and Ajzen (1974) employed a Likert scale from Bardis (1961), a Guttman scale from Faulkner and DeJong (1969), and a Thurstone scale from Poppleton and Pilkington (1963). Examination of these scales shows them to be consistent with the preceding definitions of the cognitive component. For instance, the statements employed are of the following form:

1. "Religious faith is merely another name for belief which is contrary to reason" (Poppleton & Pilkington, 1963, p. 34).

2. "Religious truth is higher than any other

form of trust" (Faulkner & DeJong, 1969, p. 567).

It is possible to distinguish empirically between the single-component and two-component views of attitude using the data of Fishbein and Ajzen (1974). To do this, one may examine and compare the convergent validity of each model. Although the Campbell and Fiske (1959) criterion of high correlations among the measures of each component provides one indication of convergent validity, the procedure is an arbitrary one, and the more rigorous confirmatory factor analysis methodology was employed in the present study. Among other benefits (cf. Bagozzi, 1978), Kenny (1976) notes the following advantages of confirmatory factor analysis:

> The application of confirmatory factor analysis to the multitrait–multimethod matrix has a number of advantages over the traditional Campbell-Fiske set of criteria: (a) Confirmatory factor analysis gives estimates of parameters while the Campbell-Fiske criteria are only rules of thumb. (b) Significance tests are possible with confirmatory factor analysis. (c) Given marked differences in the reliability of measures, the Campbell-Fiske criteria are misleading . . . while confirmatory factor analysis takes into account differential reliability. (p. 248)

To test for convergent validity using confirmatory factor analysis, the null hypotheses expressed in Figure 1 must be examined. Panel a of Figure 1 shows the null hypothesis for the single-component model. Under the single-component model, for convergent validity to be sustained, it is necessary that the responses of subjects to all attitude measures achieve a high degree of correspondence. Rather than using the criterion of correspondence suggested by Campbell and Fiske, which is not as stringent as confirmatory factor analysis and which can be misleading, as noted above, the likelihood ratio chi-square goodness-of-fit test can be used. Similarly, Panel b of Figure 1 displays the null hypothesis for the two-component model. Under this model, convergent validity will be obtained when the responses of subjects achieve a high degree of correspondence for (a) the affective component and (b) the cognitive component *and* when the correlations of attitude measures across the two components are both consistent in their pattern and significantly lower in magnitude than the within-component attitude measure correlations. Again, the likelihood ratio chi-square goodness-of-fit test can be used to test this hypothesis. The formal statement of the convergent validity null hypotheses will be made below under Method.

The data of Fishbein and Ajzen (1974) do not permit one to distinguish between the prediction that behavior is accounted for by intentions alone and the prediction that behavior is accounted for by the simultaneous consideration of the conative, cognitive, and affective components of attitude. This is because behavior and behavioral intention measures were not both obtained from the same individuals.[3] However, a finding that the cognitive and affective components of attitude simultaneously account both for behavioral intention and for verbal reports of past behavior would be consistent with the two-component view suggested here.

Attitude–Behavior Relationship

It has been argued (e.g., Ajzen & Fishbein, 1977; Fishbein, 1967a, 1973; Fishbein & Ajzen, 1974) that a major reason for the weak relationship obtained between attitude and behavior is the lack of correspondence between attitudinal predictors and behavior criteria. Fishbein (1973) notes that although a relationship is frequently assumed between attitude and whatever behavior the researcher happens to be interested in, there is no necessary relationship between a general attitude toward an object and the performance of a specific behavior with respect to that object. However, a general attitude toward an object should be predictive of the overall pat-

[3] Fishbein and Ajzen (1974) obtained self-reports of behavioral intentions from a sample of 63 subjects and self-reports of past behavior from a separate sample of 62 subjects. They argue that while both of these behavioral criteria are verbal responses, self-reports of past behavior go beyond intentions to provide meaningful approximations of behavior. More recently, Weigel and Newman (1976) employed overt behaviors as criteria, and they obtained results that are consistent with those obtained by Fishbein and Ajzen.

terns of behavior engaged in with respect to that object. In their most complete elaboration of this view, Ajzen and Fishbein (1977) maintain that "the strength of an attitude–behavior relationship depends in large part on the degree of correspondence between attitudinal and behavioral entities" (p. 891). When correspondence is high, the strength of the relationship between attitude and behavior should also be high. They suggest that attitudinal and behavioral entities may be considered in terms of four different elements: an action element, a target toward which the action is directed, a context in which the action is performed, and a time at which the action is performed. As a result, an attitude toward a specific act to be engaged in at a given time in a specific context should be predictive of the actual performance of that act in that time and situation.

However, an attitude toward an object (i.e., time, action, and context are unspecified) should not necessarily predict any particular behavior logically related to the object. One would not, therefore, necessarily expect a correlation between attitude toward an object and single-act behavior criteria or even multiple-act behavior criteria unless the content of the criteria were scaled at comparable levels of generality and/or the multiple-act criteria encompassed a wide range of relevant behaviors. The attitude employed in the present study was attitude toward "being religious" and is thus nonspecific with respect to action, context, and time. Consequently, it may be hypothesized that attitude will predict scaled multiple-act criteria but not necessarily single-act criteria or unscaled multiple-act criteria.

Fishbein and Ajzen (1974) have shown support for their contention that high correlations between measures of attitude and behavior should be expected only under conditions of high attitude–behavior correspondence. Average correlations between attitude and single-act criteria were low, ranging from .121 to .202. When a multiple-act criterion was constructed by summing responses to 100 behavioral intention statements or 100 self-reports of past behavior, the correlations between attitude and this criterion were high, ranging from .604 to .749. Similar results were obtained by Weigel and Newman (1976) in an assessment of overt behaviors obtained 3 months after administration of an attitude instrument. Fishbein and Ajzen also found that correlations between attitude and multiple-act criteria tended to be equally high and significant when the behavioral criteria were scaled in accordance with Guttman, Likert, or Thurstone scaling procedures.

It is rather surprising that correlations between attitude and scaled multiple-act criteria were not stronger than correlations obtained between attitude and a simple summative criterion. As Fishbein and Ajzen (1974) pointed out, "Many (if not most) behaviors that are performed with respect to or in the presence of a given object, *cannot* be considered valid indicants of a person's attitude towards that object" (p. 66). Use of a standard scaling procedure "is one way of insuring that the behavioral items selected constitute valid behavioral criteria, that is, that they are in some way related to the attitude under consideration" (Fishbein & Ajzen, 1974, p. 65). Fishbein and Ajzen reported that when scaling was employed, most of the 100 items were rejected by all three scaling procedures. This would suggest that most behaviors (or intentions) were unrelated to people's attitudes toward being religious. These behaviors may be performed for essentially nonattitudinal reasons. The inclusion of these behaviors in a multiple-act criterion would incorporate considerable error in the instrument. We would expect, therefore, that a strong relationship would be obtained between attitude and behavior only when both attitude and the multiple-act criterion are appropriately scaled (see discussion below and under Method).

To test for the predictive validity of the attitude–behavior relationship using confirmatory factor analysis, the null hypotheses of Figures 2 and 3 must be investigated. Although a formal, detailed description of these hypotheses will be provided in the Method section, for now it should be noted that the path diagrams provide a representation of the relationship between attitude as a *construct* and the appropriate behavior criterion. The construct to use in these hypotheses is the one achieving convergent validity. Intuitively, the

null hypotheses entailed by Figures 2 and 3 state that the more favorable the attitude, A, the greater the number of behaviors, B, performed. The parameter γ represents the degree of predictive validity and is analogous to a beta coefficient in regression. It should be stressed, however, that the hypotheses in confirmatory factor analysis are more stringent than those suggested by, say, correlation or regression analyses. That is, a failure to reject the null hypotheses implied by Figures 2 and 3 requires that the relationship γ be statistically significant *and* that (a) the intercorrelations among the attitude measures of A achieve a high degree of correspondence, (b) each measure of A relate to the behavioral criteria in a statistically significant and sufficiently large way, and (c) the pattern of intercorrelations between measures of A and B be uniform. The likelihood ratio chi-square goodness-of-fit test can be used to evaluate this hypothesis.

Notice that it is possible for each individual attitude measure to correlate highly with the behavior criterion, yet if the pattern of intercorrelations is not consistent, then one would reject the null hypothesis. This condition is analogous to Campbell and Fiske's (1959) rule of thumb that "the same pattern of trait interrelationship be shown in all of the heterotrait triangles of both the monomethod and heteromethod blocks" (p. 83). This aspect of the null hypotheses is also what is meant, in part, by Kenny's (1976) observation that confirmatory factor analysis "takes into account differential reliability" (p. 248). With regard to the attitude–behavior relationship, it is hypothesized that the attitude *construct* will not predict the single-act or multiple-act behavior criteria even though correlations between individual measures of attitude and single acts or multiple acts might be significant. Because the correspondence between the attitude measures and both the single-act criterion (i.e., the mean correlation with 100 behaviors) and the multiple-act criterion (i.e., the sum over 100 behaviors) is low (in the sense of being at different levels of specificity with regard to time, action, and context), one would not expect the pattern of correlations between measures of A and B to be uniform. Consequently, it is hypothesized that the relationship between attitude and single-act and multiple-act behavior criteria should be rejected. In contrast, it is hypothesized that the relationship between attitude and *scaled* multiple-act criteria will be sustained, because the attitude and behavior measures are formed at comparable levels of specificity.

In sum, we expected that a reanalysis of the Fishbein and Ajzen (1974) data using confirmatory factor analysis would support the following hypotheses:

1. Convergent validity will be obtained when the cognitive and affective measures of attitude are treated as separate components, but convergent validity will not be obtained when all five instruments are treated as alternative measures of the same underlying construct.
2. The attitude *construct* will not predict single-act behavior criteria.
3. The attitude *construct* will not predict multiple-act behavior criteria.
4. The attitude *construct* will predict scaled multiple-act behavior criteria.

Method

Data Source

To test the hypotheses, a reanalysis of data reported in Fishbein and Ajzen (1974) was performed. Fishbein and Ajzen had used two samples of respondents. In the first, 62 male and female undergraduates indicated which items from a set of 100 behaviors they had performed (the self-reported behaviors sample). The set of behaviors consisted of a list of 70 actions dealing with religious matters (e.g., pray before or after meals, donate money to a religious institution, etc.) and 30 additional actions in a refusal format selected from the original 70 (e.g., refuse to state a religious preference during university registration). The second sample was composed of 63 male and female undergraduates who indicated which items from the set of 100 behaviors they would perform (the behavioral intentions sample).

In addition, all subjects completed five scales measuring attitudes toward religion. A Guilford self-rating scale measured attitudes towards being religious on an 11-point scale ranging from extremely favorable to extremely unfavorable. A semantic differential scale measured evaluations of "being religious" on five 11-point bipolar scales having the following endpoints: good–bad, harmful–beneficial, wise–foolish, pleasant–unpleasant, and sick–healthy. The Guilford and semantic differential scales are considered in the present study to tap the affective dimensions

of attitudes. Support for this contention was provided in the preceding sections of this article.

To measure the cognitive component of attitude toward religion, three standard religiosity scales were employed. These included Likert (Bardis, 1961), Guttman (Faulkner & DeJong, 1969), and Thurstone (Poppleton & Pilkington, 1963) scales.

The Fishbein and Ajzen (1974) data set provide a better test of the predictive validity of attitude than the data of either Kothandapani (1971) or Osrom (1969). This is because Kothandapani used a single dichotomous measure of behavior (i.e., used or did not use contraceptives) and Ostrom employed eight measures of religious behaviors but had to omit 44

subjects who completed the attitude scales but failed to complete all of the behavioral self-reports. The Fishbein and Ajzen data offer the advantages of 100 measures of behavior or behavioral intentions with no attrition.

Methods of Analysis

Convergent validity. Before a test can be made of hypotheses relating attitude to behavior, it is necessary to establish the validity of the attitude measures. Although a full test of construct validity would require the use of the multitrait–multimethod matrix design (cf. Ostrom, 1969), this was not possible in the present study because the same set of multiple measures was not used on each of the hypothesized attitudinal components. However, because two measures of affect and three measures of beliefs were obtained, it is possible to ascertain the degree of convergent validity for the attitudinal measures.

Two rival models bear upon the issue of convergence in the present research. The first is termed the single-factor model and hypothesizes that the variance in individual responses (except for random error in measurement) is accounted for by one underlying attitudinal construct. Panel a of Figure 1 depicts the single-factor model, in which the five attitudinal scales are shown measuring one overall attitudinal construct, affective and cognitive (i.e., A_{a+c}). Random error in measurements is indicated by the *z*s. The single-factor model is the attitude model implicitly employed by Fishbein and Ajzen (1974), in that they did not differentiate the five scales into affective and cognitive dimensions but rather treated all five as independent measures of the same underlying "attitude towards religion" construct. Panel a of Figure 1 represents a diagram of a hypothesis that can be used to test Fishbein and Ajzen's (1974) assumption.

The two-factor model (Figure 1, Panel b) posits that attitudes are represented as two conceptually independent, yet empirically related, constructs: (a) an affective component (A_a) and (b) a cognitive or belief dimension (A_c). The empirical correlation between A_a and A_c is shown as $\phi_{A_aA_c}$.

As a point of interpretation, it should be noted that the path diagrams in Figure 1 follow current practice in the confirmatory factor analysis literature in that they represent null hypotheses to be tested on data (cf. Jöreskog, 1969; Kenny, 1976). Although the application of confirmatory factor analysis does not permit one to discriminate *between* the single- and two-factor models per se, it does allow the researcher the opportunity of examining both the single-factor model as a null hypothesis and the two-factor model as a null hypothesis. The confirmatory factor analysis in the present context permits the researcher to test whether the one-factor, the two-factor, or both the one-factor and two-factor models are consistent with the data. In this way, the procedures yield an empirical test of the convergent validity for each attitude model and can be used to identify internally consistent constructs. The test is important to apply before investigation of the relationship between attitude and behavior because it is a matter of logical and empirical necessity that convergent validity be achieved in order for one to accept the theoretical and predictive utility of the attitude model. If one or both of the convergent validity hypotheses were rejected, then it would not be legitimate to examine further hypotheses as to the predictive validity of the nonconvergent attitudinal construct. In the present investigation, it is suggested that the two-component, but not the single-component, model will achieve convergent validity.

To test the models of Figure 1, the following general confirmatory factor analysis model can be examined:

$$y = \Lambda x + z, \tag{1}$$

where y is the vector of p attitude measures; x is a $k < p$ vector of hypothesized attitude components; k is the number of attitude components; z is a vector of p unique scores (i.e., errors in measurement); and Λ is a $p \times k$ matrix of factor loadings relating attitude measurements to their respective components. For Figure 1, Panel a, $p = 5$ and $k = 1$, while for Figure 1, Panel b, $p = 5$ and $k = 2$. With the assumptions that $E(x) = E(z) = 0$ (i.e., measures are expressed as deviations from their means), $E(xx') = \phi$ (where ϕ is the intercorrelation between attitude components), and $E(zz') = \psi$ (where ψ is a diagonal matrix of error variances), the variance-covariance matrix of measurements, Σ, may be expressed as

$$\Sigma = \Lambda\phi\Lambda' + \psi. \tag{2}$$

Jöreskog (1969) derives a maximum likelihood procedure for estimating the parameters in Λ, ϕ, and ψ. Further, the methodology yields an overall chi-square goodness-of-fit measure that tests the null hypothesis specified by Figure 1 and Equations 1 and 2 against the alternative hypothesis that the variance–covariance matrix is any positive definite matrix. The computer program LISREL can be used to test the models of Figure 1 and Equations 1 and 2 (cf. Jöreskog & van Thillo, 1972).

Single-act and multiple-act criteria. To test the hypotheses that attitude predicts single-act and multiple-act behavioral criteria, the path model of Figure 2 was used. In this figure, A represents the attitude construct achieving convergent validity; B stands for the appropriate single-act or multiple-act criterion measures; and n attitude measures (i.e., y_is) are drawn to indicate that the test applies to the general case. The single-act behavioral criterion measures are simply the individual responses to each of the 100 self-reports of behaviors or behavioral intention. The multiple-act behavioral criterion measure is the sum over 100 self-reports of behaviors or behavioral intentions.

In the present study, it is hypothesized that the attitude construct will not act as a significant predictor of either single-act or multiple-act behavioral

criteria (see the earlier discussion on attitude–behavior hypotheses). Looking first at the relation between attitude and the single-act behavioral criterion, it is expected that the relationship will be weak or nonsignificant because the degree of correspondence between attitude and behavior is minimal (see earlier comments and comments in Discussion section). This hypothesis is the same as that posed by Fishbein and Ajzen (1974).

Looking next at the relation between attitude and the multiple-act behavioral criterion, however, it is hypothesized that the overall predictive model of Figure 2 will be rejected despite the presence of high absolute correlations between each individual attitude measure and the multiple-act criterion measure. This perhaps counterintuitive hypothesis is contrary to that suggested by Fishbein and Ajzen (1974). The rationale for this hypothesis is that the high observed correlations between each individual attitude measure and the multiple-act criterion arise as a consequence of the definition and operationalization of the multiple-act criterion. Because this criterion is defined as the sum of occurrences over 100 different behaviors, it is probable that each respondent's score expresses a different set of behaviors, and thus the numerical value for the multiple-act criterion assigned to each person would represent an inconsistent mapping in measurement. Two or more people can have identical scores on the multiple-act criterion yet exhibit vastly different behaviors as a function of the content of their responses. As a result, the procedure used to construct the criterion violates the rule of numerical assignment theory that requires a 1:1 correspondence between number and referent. Even though one expects high correlations between individual measures of attitude and the criterion, it can be anticipated that the entire pattern of correlations among attitude measures and the criterion would not be consistent with the model hypothesized in Figure 2.

To test the model of Figure 2, Jöreskog's (1970) analysis of covariance structures methodology can be used in conjunction with LISREL. The appropriate model to test is

$$B = \gamma A + \zeta \tag{3}$$

$$\begin{bmatrix} y_1 \\ y_2 \\ \cdot \\ \cdot \\ \cdot \\ y_n \\ y_b \end{bmatrix} = \begin{bmatrix} \alpha_1 & 0 \\ \alpha_2 & \cdot \\ \cdot & \cdot \\ \cdot & \cdot \\ \cdot & \\ \alpha_n & 0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} A \\ B \end{bmatrix} + \begin{bmatrix} z_1 \\ z_2 \\ \cdot \\ \cdot \\ \cdot \\ z_n \\ 0 \end{bmatrix}, \tag{4}$$

where B is the appropriate single-act or multiple-act behavioral criterion; A is the attitude component achieving convergent validity in the previously described tests; γ is a parameter analogous to a regression coefficient relating attitude to behavior; ζ is a random error in equation term; $y_1, y_2, \ldots, y_n$ are n attitude measurements; y_b is the actual behavioral criterion measure; the αs are parameters relating A to its measures; and the zs are random measurement errors.

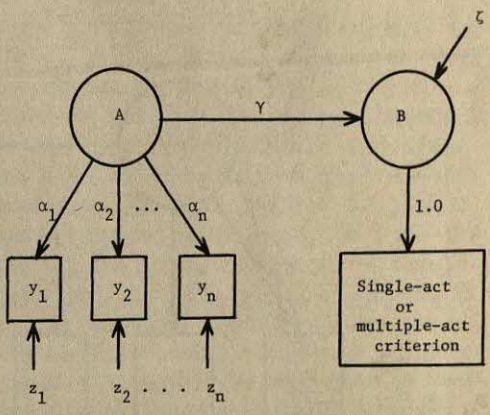

Figure 2. Path diagram for testing validity of single-act and multiple-act criteria models of behavior. (A = attitude construct; B = behavior criterion. The remaining symbols represent parameters to be estimated and are defined in the text.)

Prediction of scaled behavior. To test the hypothesis that attitude predicts scaled behavioral measures, the path diagram of Figure 3 may be used. In contrast to the single-act and multiple-act behavioral criteria, the scaled behaviors are meaningful measures and approach the same level of specificity as the attitudinal scales. For a description of the scaling procedures used, the reader is referred to Fishbein and Ajzen (1974). Although Fishbein and Ajzen hypothesized that attitude would predict scaled behavioral measures, they tested the hypothesis only by examining the individual correlations between each attitude measure and each scaled behavior measure. A more rigorous and meaningful test of the hypothesis can be performed by using the general analysis of covariance structures model, which is a generalization of confirmatory factor analysis. This method examines the entire pattern of intercorrelations as a unit rather than examining only the individual relationships. Further, it provides a chi-square goodness-of-fit test, estimates parameters, and takes into account differential reliability, as noted earlier. The appropriate equations to test are

$$B_s = \gamma A + \zeta \tag{5}$$

$$\begin{bmatrix} y_1 \\ y_2 \\ \cdot \\ \cdot \\ \cdot \\ y_n \\ y_{n+1} \\ \\ y_{n+2} \\ \cdot \\ \cdot \\ \cdot \\ \\ y_{n+m} \end{bmatrix} = \begin{bmatrix} \alpha_1 & 0 \\ \alpha_2 & 0 \\ \cdot & \cdot \\ \cdot & \cdot \\ \cdot & \cdot \\ \alpha_n & 0 \\ 0 & \lambda_1 \\ \\ \cdot & \\ \cdot & \lambda_2 \\ \cdot & \cdot \\ & \cdot \\ 0 & \lambda_m \end{bmatrix} \begin{bmatrix} A \\ B_s \end{bmatrix} + \begin{bmatrix} z_1 \\ z_2 \\ \cdot \\ \cdot \\ \cdot \\ z_n \\ \epsilon_1 \\ \epsilon_2 \\ \cdot \\ \cdot \\ \cdot \\ \epsilon_m \end{bmatrix}, \tag{6}$$

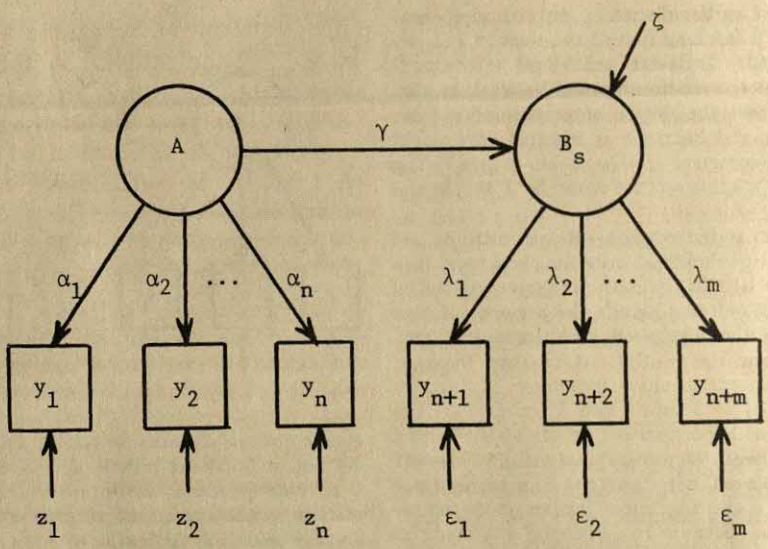

Figure 3. Path diagram for determining the relationship between attitudes and scaled measures of behavior. (A = attitude construct; B_s = scaled multiple-act behavior criterion. The remaining symbols represent parameters to be estimated and are defined in the text.)

where B_s is the scaled behavioral construct; A is the attitude component; $y_1, y_2, \ldots, y_n$ are the n measures of A: $y_{n+1}, y_{n+2}, \ldots, y_{m+n}$ are the m measures of B_s; the αs and λs are parameters relating A and B_s to their respective measures; the z and ϵ are random measurement errors; and γ and ζ are defined as above.

Results

Table 1 summarizes the intercorrelations of variables for both samples. Looking at these correlations, Fishbein and Ajzen (1974) concluded that the five verbal attitude scales showed "a high degree of convergent validity" and "all attitude scales correlated highly with the multiple-act criterion, while the prediction of single-act criteria tended to be low and nonsignificant" (p. 62). The latter was taken as evidence that a person's attitude towards an object should be related to the overall pattern of one's behaviors but not necessarily to

Table 1
Intercorrelations of Verbal Attitude Scales, Single-Act and Multiple-Act Behavioral Criteria, and Behavioral Scales[a]

Variable	1	2	3	4	5	6	7	8	9	10
1. Self-report	—	.800	.519	.652	.584	.137	.640	.451	.582	.701

[a] Above diagonal for respondents indicating self-reported behaviors (n = 62); below diagonal for respondents indicating behavioral intentions (n = 63).
[b] $r_{.05}$ = .250; $r_{.01}$ = .325.
[c] Mean correlation with 100 behaviors or intentions.
[d] Sum over 100 behaviors or intentions.

any single behavior that may be performed with respect to the object. Each of these hypotheses and the ones relating attitude to scaled behavior measures are examined below using the more rigorous confirmatory factor analysis methodology. An extension of the attitude model is also investigated.

Convergent Validity

Single-factor model. Application of the confirmatory factor analysis model of Figure 1, Panel a and LISREL to the data shows that the hypothesis of convergent validity must be rejected for both the self-reported behaviors sample, $\chi^2(5) = 23.91$, $p < .01$, and the behavioral intentions sample, $\chi^2(5) = 13.98$, $p < .01$. Thus, contrary to the original claim made by Fishbein and Ajzen (1974), one cannot accept the hypothesis that the five attitudinal scales are measures of a single underlying attitude construct.

Two-factor model. Given the failure to achieve convergent validity for the single-factor model, the two-factor, two-component model was tested (Figure 1, Panel b). Application of LISREL to the data indicates that the hypothesis of convergent validity is supported for the self-reported behaviors sample, $\chi^2(4) = 2.30$, $p \simeq .68$, and the behavioral intentions sample, $\chi^2(4) = 8.30$, $p \simeq .08$.[4] Hence, convergent validity is established for the two-component model but not for the single-component model. Further analysis of the predictive validity of attitude in the present study is thus justified only for the two-component conceptualization of attitude.

Prediction of Behavior: Single-Act and Multiple-Act Criteria

Single-act criterion. As posited, the hypothesis maintaining that attitude will be a significant predictor of single-act criterion measures was not supported. Looking first at the self-reported behaviors sample, it can be seen that—although the pattern of correlations among attitude and behavioral criterion measures was consistent with predictions using either affect, $\chi^2(1) = .02$, $p \simeq .89$, or cognitions, $\chi^2(3) = .05$, $p \simeq .99$, as predictors[5] —the standardized parameter estimates for the γs, relating attitude to behavior, were insignificant, $\gamma_a = .157$, *ns*; $\gamma_c = .148$, *ns*. Similarly, looking at the behavioral intentions sample, it can be observed that—despite finding a pattern of correlations consistent with predictions for affect, $\chi^2(1) = .04$, $p \simeq .83$, and cognitions, $\chi^2(3) = .34$, $p \simeq .95$—the standardized parameter estimates, γs, were insignificant, $\gamma_a = .190$, *ns*; $\gamma_c = .193$, *ns*. In sum, it was found that attitude does not act as a significant predictor of single-act criterion measures. These results are typical of that found in the literature relating attitude to single-act behaviors (cf. Wicker, 1969).

Multiple-act criterion. Although Table 1 indicates that high correlations exist between each of the five measures of attitude and the multiple-act behavior criterion, this does not necessarily imply that the attitude construct itself will be related validly to the multiple-act behavior criterion. The prediction of behavior indicated by Figure 2 requires that the entire pattern of correlations among all measurements meet a set of logical and empirical conditions. Not only must the correlations among

---

[4] Although the chi-square value for the behavioral intentions sample indicates a borderline fit (i.e., $p \simeq .08$), when Bartlett's (1951) small-sample correction factor is applied, the model reaches acceptable levels of significance, $\chi^2(4) = 7.65$, $p \simeq .10$.

[5] To test the prediction of behavior hypotheses, each attitude component was examined as a separate predictor rather than observing both simultaneously. This was done in order to avoid what Burt (1976) terms "interpretational confounding." Interpretational confounding is similar in form to the problem of multicollinearity in multiple regression analysis, and the condition can affect the precision of the parameter estimates relating attitude to behavior. Briefly, the problem arises because of the structure of intercorrelations among attitude and behavior measures. Logical considerations dictate that measures of the same construct should correlate highly among themselves and that most, if not all, correlations between measures of different constructs should be lower than the within-construct correlations (Campbell & Fiske, 1959). However, as shown in Table 1, many of the cross-construct correlations that include the criterion measure violate this rule, even though the criterion correlates highly with all measures of attitudes in an absolute sense. As a result, to examine the validity of attitude as a predictor of behavior, it is more meaningful to examine the predictive ability of the affective and cognitive components separately.

attitude measures be significant and achieve convergence, but simultaneously the composition of correlations between each attitude measure and the criterion must be consistent with the structure implied by Figure 2. It is hypothesized, however, that the construction of the multiple-act criterion will not sustain the prediction of behavior because the content of the criterion measure fails to achieve construct validity and is not at the same level of specificity as the attitude construct.

Application of Jöreskog's analysis of covariance structures to the data and the model of Figure 2 shows that the hypothesis referring to the prediction of the multiple-act criterion must be rejected, as maintained. Looking first at the self-reported behaviors sample, the hypothesis is rejected for both the model using affect as a predictor, $\chi^2(1) = 14.05$, $p < .01$, and the model using cognitions as a predictor, $\chi^2(3) = 12.89$, $p < .01$. Similarly, for the behavioral intentions sample, the hypothesis must be rejected for both the model using affect as a predictor, $\chi^2(1) = 10.93$, $p < .01$, and the model using cognitions as a predictor, $\chi^2(3) = 21.41$, $p < .01$.

Prediction of Behavior: Scaled Behavior Measures

As posited, the hypothesis that attitude will predict scaled behavior was supported (see Figure 3). Looking first at the self-reported behaviors sample, it can be seen that the hypothesis [6] is supported for (a) the model with affect as a predictor and either Guttman and Likert scaled behavior as a criterion, $\chi^2(1) = 1.01$, $p \simeq .32$, or Likert and Thurstone scaled behavior as a criterion, $\chi^2(1) = 2.77$, $p \simeq .10$, and (b) the model with cognitions as a predictor and either Guttman and Likert scaled behavior as a criterion, $\chi^2(4) = 5.38$, $p \simeq .25$, or Likert and Thurstone scaled behavior as a criterion, $\chi^2(4) = .85$, $p \simeq .93$. Similarly, for the behavioral intentions sample, the hypothesis is supported for (a) the model with affect as a predictor and either Guttman and Likert scaled behavior as a criterion, $\chi^2(1) = 1.38$, $p \simeq .24$, or Likert and Thurstone scaled behavior as a criterion, $\chi^2(1) = .14$, $p \simeq .71$, and (b) the model with cognitions as a predictor and either Guttman and Likert scaled behavior as a criterion, $\chi^2(4) = 6.35$, $p \simeq .17$, or Likert and Thurstone scaled behavior as a criterion, $\chi^2(4) = 4.79$, $p \simeq .31$.

To examine the joint effect of affect and cognitions on scaled behavior, the path model of Figure 4 can be used.[7] The structural equations for this model can be written as

$$B_s = (\gamma_1 \gamma_2) \begin{bmatrix} A_a \\ A_c \end{bmatrix} + \zeta \tag{7}$$

$$\begin{bmatrix} L_B \\ T_B \end{bmatrix} = \begin{bmatrix} \lambda_1 \\ \lambda_2 \end{bmatrix} B_s + \begin{bmatrix} \epsilon_1 \\ \epsilon_2 \end{bmatrix} \tag{8}$$

$$\begin{bmatrix} SR \\ SD \\ G \\ L \\ T \end{bmatrix} = \begin{bmatrix} \alpha_1 & 0 \\ \alpha_2 & 0 \\ 0 & \alpha_3 \\ 0 & \alpha_4 \\ 0 & \alpha_5 \end{bmatrix} \begin{bmatrix} A_a \\ A_c \end{bmatrix} + \begin{bmatrix} z_1 \\ z_2 \\ z_3 \\ z_4 \\ z_5 \end{bmatrix}, \tag{9}$$

where B_s is the scaled behavior construct; A_a and A_c are the affective and cognitive components of attitude, respectively; L_B and T_B

---

[6] Predictive validity models are run with the Guttman/Likert and Likert/Thurstone operationalizations rather than with a single Guttman/Likert/Thurstone operationalization of behavior because inspection of the correlation matrix in Table 1 reveals that the Guttman and Thurstone measures correlate at a lower level than the other two pairs of correlations in both samples. As Burt (1976) notes, such a pattern of intercorrelations among the measures of the same construct can result in "interpretational confounding," pariticularly if each measure correlates at a different degree with a criterion measure. The details of this confounding are quite mathematically complex, and for a complete description of the problem, the reader is referred to Burt (1976). At an intuitive level, what interpretational confounding means in the present context is that the covariances of the measures of behavior with the attitude measures are not proportional but reflect some unmeasured influence such as excessive measurement error. The condition is present only when all three measures of behavior are present or when the Guttman and Thurstone scales are used. The condition is not present when the Guttman/Likert and Likert/Thurstone combinations are employed. Hence, the predictive validity models were examined with the latter two measures of behavior.

[7] The joint effect of affect and cognitions on scaled behavior should be interpreted with caution. The procedure should be employed only when interpretational confounding is not a serious problem (Burt, 1976). See Footnote 5.

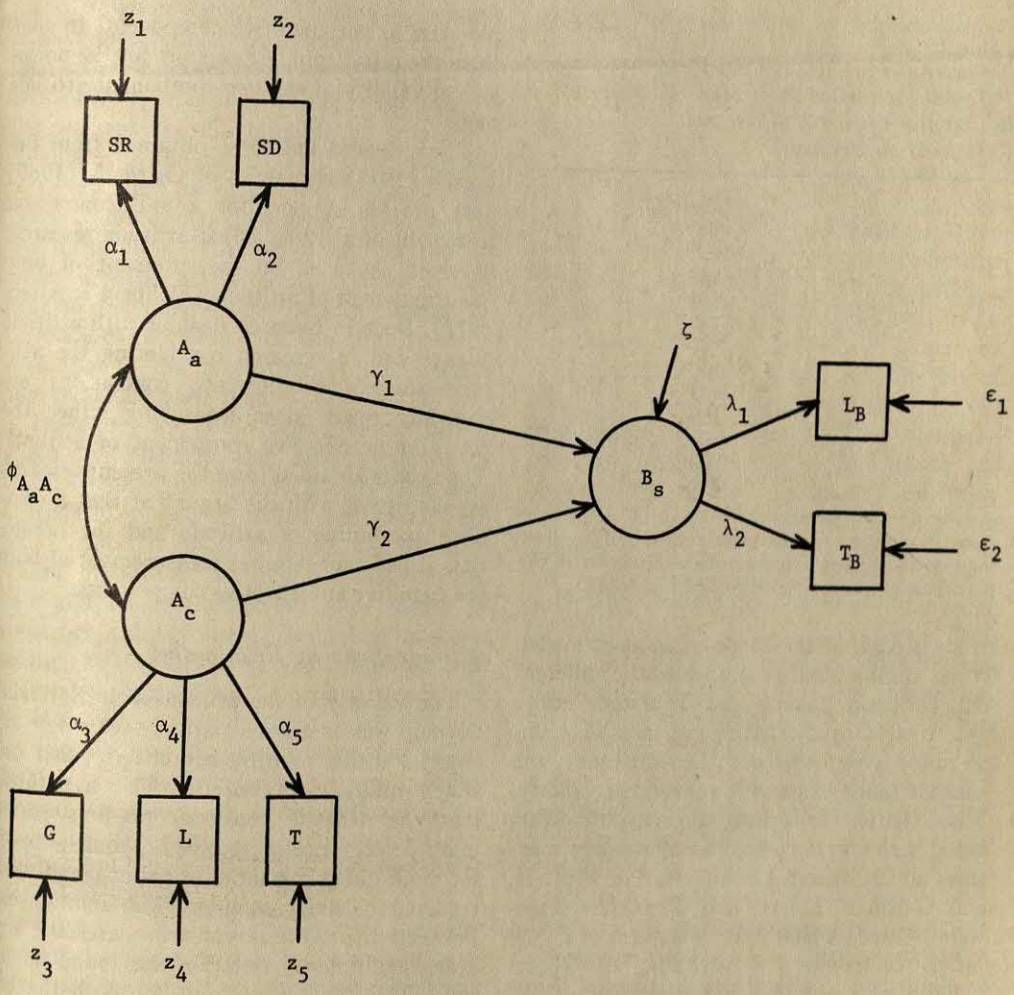

Figure 4. Testing for the relative impact of affect and cognitions on behavior. (A_a = affective attitude component; A_c = cognitive attitude component; B_s = scaled multiple-act behavior criterion; L_B = Likert scaled behavior measure; T_B = Thurstone scaled behavior measure; SR = Guilford self-report, SD = semantic differential, G = Guttman, L = Likert, and T = Thurstone scales. The remaining symbols represent parameters to be estimated and are defined in the text.)

are the Likert and Thurstone scaled behavior measures, respectively; SR = Guilford self-report, SD = semantic differential, G = Guttman, L = Likert, T = Thurstone scales; and the remaining symbols are as defined earlier.

Application of Jöreskog's analysis of covariance structures to the data and model of Figure 4 yields the results shown in Table 2 where, because of problems of interpretational confounding, only the findings for the self-reported behaviors sample are displayed. In general, the model fits the data well, $\chi^2(10) = 13.11$, $p \simeq .22$. Further, the affective component can be seen to be approximately three times as forceful in its impact on behavior as the cognitive component ($\gamma_1 = .651$ and $\gamma_2 = .226$).

Discussion

Attitude Organization

The results obtained from a reanalysis of the Fishbein and Ajzen (1974) data support a two-component model of attitude and lead

to a rejection of the single-component model. When Guilford self-rating, semantic differential, Guttman, Likert, and Thurstone scales were treated as alternative measures of a single underlying construct (i.e., attitude), the analysis failed to provide convergent validity. When Guilford self-rating and semantic differential scales were treated as alternative measures of an affective component of attitude, and Guttman, Likert, and Thurstone scales were treated as alternative measures of a cognitive component of attitude, convergent validity was obtained. The validity of the two-component model was supported for the self-report and behavioral intention samples.

Further support for the validity of the two-component model is provided by a consideration of nomological validity. Following Campbell (1960), nomological validity is defined as the degree to which predictions from a concept in a theoretical system of concepts are confirmed. It was found that each component of the two-component model separately predicted scaled multiple-act criteria. Furthermore, both components contributed simultaneously to the prediction of behavior. Because of interpretational confounding, only self-report data were employed in the latter analysis. While both components simultaneously accounted for behavior, the affective component was approximately three times as powerful as the cognitive component. In sum, then, the results provide support for the nomological validity of the two-component attitude model.

These results and those obtained from Bagozzi's (1978) reanalysis of Ostrom's (1969) data provide support for a multicomponent treatment of attitude. Most attitude research, however, is based on measurement of only one component of attitude (Fishbein & Ajzen, 1975). Both in research dealing with attitude change and in research considering the attitude–behavior relationship, conclusions are generally made after measuring either the cognitive or affective component of attitude. The results obtained from the present research are consistent with the argument that a complete accounting of attitude and the prediction of behavior requires measurement of both the cognitive and affective components.

Attitude–Behavior Relationship

The validity of the attitude–behavior relationship was assessed separately for single-act criteria, scaled multiple-act criteria, and unscaled multiple-act criteria. The hypothesis that the attitude construct predicts scaled multiple-act criteria received strong support for both the behavioral intentions and self-reported behavior samples. The relationship between the attitude construct and the unscaled multiple-act criterion was found not to hold. This finding was true for both the behavioral intention and self-reported behavior samples. Finally, as predicted, the relationship between the attitude construct and single-act criteria was found not to hold in either sample.

These results provide partial support for Ajzen and Fishbein's (1977) contention that the strength of the attitude–behavior relationship is directly related to the degree of correspondence between "attitudinal and behavior entities." According to Ajzen and Fishbein's conceptualization, however, correspondence should also be high for the multiple-act criterion derived from summation across all 100 behaviors, because the action, context, and time elements are left unspecified in both the attitudinal and behavioral entities. Even though correspondence was high in this sense,

the summation across 100 behaviors is likely to have incorporated considerable error in the final criterion score. In an earlier paper, Fishbein (1973) notes that scaling is necessary in the construction of a multiple-act criterion to eliminate invalid items (i.e., items unrelated to favorability for or against the concept under consideration). The error introduced by the inclusion of "invalid items" in the unscaled multiple-act criterion is likely to have lead to an inconsistent pattern among the correlations between attitude and behavior even though the magnitude of the relationship remained quite high.

Therefore, we would argue, in contrast to Ajzen and Fishbein, that correspondence between attitude and behavior is only high when attitude is related to scaled multiple-act criteria. The attitudinal construct was based on scaling procedures that ensured that only beliefs and feelings achieving some degree of construct validity were used. The unscaled multiple-act criterion was not based on such a restrictive procedure. Correspondence will be high only when the behavioral entity is also based on scaling procedures that ensure that the criterion achieves convergent validity and the content of the attitudinal and behavioral items is at comparable levels of generality. This was found only for the scaled multiple-act criteria.

Failure to sustain the validity of the relationship between attitude and single-act criteria provides further support to Fishbein and Ajzen's argument that a general attitude bears no necessary relationship to single-act criteria. This does not alter the frequently obtained finding of significant relationships between attitude and single acts (i.e., Campbell et al., 1960; Fishbein & Ajzen, 1974). It does point out, however, that these relationships cannot be automatically assumed. The question remains as to how we can determine which single acts can be expected to bear a valid relationship to attitude.

Failure to obtain direct relationships between general attitude and single acts may be due to the fact that frequently little a priori thought is given to why a relationship should logically be expected between attitude and action in a given context and time. Not only should a rationale exist for hypothesizing a specific link between attitude and single acts, but other nonattitudinal factors should also be considered. Normative prescriptions and social constraints have frequently been identified as factors that moderate the strength of the attitude–behavior relationship (e.g., Gross & Niman, 1975; Kelman, 1974; Liska, 1974; Wicker, 1969).[8] We may suggest that the attitude–behavior relationship will be strong to the extent that the behavior does not involve inconsistent social or normative constraints. Warner and DeFleur (1969) provide support for the contention that the attitude–behavior relationship will be stronger when normative pressures are consistent with attitude and weaker when normative pressures are inconsistent with attitude. Similar results have been obtained by Schofield (1975). In contrast to such public behaviors as appearing in a photograph with a member of another racial group (cf. Linn, 1965), voting behavior takes place in the privacy of the voting booth. Strong relationships have been obtained between attitude toward a candidate and the act of voting for that candidate (e.g., Campbell et al., 1960). It may be, then, that those behaviors most directly related to attitude toward religion are behaviors toward religion that are either private or in other respects unlikely to be subject to inconsistent normative pressures. While it is beyond the purpose of this article to develop and test the implications of a priori criteria that will affect predictions of whether a behavior will be related to attitude, it is suggested that continued consideration of the meaning of single acts in conjunction with these and other moderating variables would further our understanding of the attitude–behavior relationship.

Further study of behaviors unrelated to attitude would also be desirable. Most behaviors employed in the Fishbein and Ajzen (1974) study were rejected by all three scal-

[8] It has also been maintained that other attitudes and motives are important mediators of the attitude–behavior relationship and that the behaviors must be perceived to be relevant to the attitude (i.e., Gross & Niman, 1975; Insko & Schopler, 1967; Kelman, 1974; Liska, 1974; Wicker, 1969).

ing procedures and were essentially unrelated to attitude. Nevertheless, performance of these behaviors may be strongly related to other psychologically relevant dimensions such as motivation, attribution processes, or personality variables. If we are to enhance our understanding of and ability to predict behavior, then it would seem desirable to direct further attention to psychological dimensions (other than attitude) accounting for behavior.

Conclusion

This study was directed at further clarifying attitude organization and attitude–behavior issues. Evidence was obtained to support an affective–cognitive conceptualization of attitude. Convergent validity was obtained for this two-component model, and it was found that attitude accounted for self-reported behavior and for behavioral intentions. It was suggested that further research with attitude should include measures of both components and treat them as simultaneous predictors of behavioral criteria.

Strong support was found for the hypothesis that attitude would predict scaled multiple-act criteria. Criteria based on summation over a large set of behaviors were found not to be related systematically to the attitude construct. Furthermore, the hypothesis that attitude would predict single-act criteria was not supported. These findings provide partial support for Ajzen and Fishbein's concept of attitude–behavior correspondence and lead to further specification of this concept. It was suggested that correspondence (in the sense of comparable levels of specificity in context, time, and action between attitude and behavior) is high, and hence a strong empirical attitude–behavior relationship can be expected, only when both attitudinal and behavioral entities are appropriately scaled.

The failure to support a valid general attitude – single-act criteria relationship—even though some single acts were directly related to attitude—led to a consideration of factors likely to result in strong behavior relationships. It was speculated that a strong relationship would be forthcoming when the target elements of the attitude and behavior correspond and when the behavior under consideration is relatively devoid of normative constraints.

Special Section on Interpretive Controversies in Personality and Social Psychology

Editor's Foreword

The convergence of 13 articles on five interpretive controversies in this issue of the *Journal of Personality and Social Psychology* has been a product of coincidence and necessity more than design. Several of the articles were ready for appearance in this issue in the normal course of publication scheduling. The others were made ready in time for this issue as a consequence of its being the last issue to appear under the present editorship. (Acting Editor Clyde Hendrick and a new editorial board assume responsibility starting with next month's issue.) The several authors, JPSP's Topic Editors, and the American Psychological Association's Central Office staff are due thanks for their cooperation in preparing several of the articles in time for appearance in this special section.

The Special Section was edited using a novel strategy for preparing and presenting controversial exchanges. In preparing the articles, parties to each exchange were asked to read each others' prepublication drafts in order to bring to the editor's attention misstatements of each others' positions. Insofar as was possible—and because of disagreements between authors, it was not always possible—apparent misstatements were modified or deleted prior to publication. It was hoped that this procedure would permit the exchange to be focused on the substance of the interpretive issues and would minimize debate over peripheral matters. In publishing the articles, a novel format was used to avoid an obvious last-word advantage for any author. The author (Author A) of the first-submitted article in an exchange was not invited to write a rebuttal article in response to an accepted reply (by Author B). Rather, Author A was instead given the opportunity to add a postscript to the originally accepted article. The major ground rule for such postscripts was that they could indicate responses to arguments presented in Author B's reply, but not in such a way as to bring in new issues that might legitimate further comment by Author B.

Experience with the articles in this special section suggests that the editorial strategy that was employed requires more effort by authors and editors than does the more usual article–reply–rejoinder format. This effort is justified only if readers find the exchanges prepared in this fashion to be especially useful. Readers are therefore requested to direct evaluative reactions to the Chief Editorial Advisor, American Psychological Association, 1200 Seventeenth Street N.W., Washington, D.C. 20036.—A.G.G.

A Reply to Norman H. Anderson's Critique of the Subject–Verb–Object Approach to Social Cognition

Harry F. Gollob
University of Denver

The Subject–Verb–Object (S–V–O) approach to social cognition provides a method of conceptualizing several social cognition problems within the context of item sets that contain eight subject–verb–object sentences, such as "The kind man avoided the intelligent swindler" and "Conservative voters enjoy golf." Anderson recently criticized the S–V–O model on numerous grounds that were primarily technical in nature. The present reply refutes all of Anderson's major criticisms. In discussing an alternative to the S–V–O model, Anderson recommends that problems raised by the pervasive tendency of subjects to respond to information configurally be dealt with by collecting data that can be described by simple algebraic models. It is argued that Anderson's alternative avoids, rather than deals with, the important issues raised by the configural responding of subjects. Although the specific content of the present article is primarily concerned with the S–V–O model, much of the discussion is relevant to issues of general importance to investigators who use analysis of variance models and/or simple algebraic models in their work. A postscript replies to the article by Anderson that follows this one.

Anderson (1977) recently wrote a detailed critique of Gollob's (1974a, 1974b) Subject–Verb–Object (S–V–O) approach to social cognition as well as of Wyer's (1975) and Insko, Songer, and McGarvey's (1974) applications of that approach. Wyer and his co-workers (Wyer, 1974, 1975; Wyer, Henninger, & Wolfson, 1975) have extended Gollob's model and have applied it in a broad variety of areas concerned with social inference and attribution theory. Insko et al. applied the S–V–O model to the analysis of pleasantness judgments in a traditional balance-theory paradigm.

In his critique, Anderson claims that Gollob and his colleagues have used analysis of variance techniques inappropriately by failing to use tests of goodness of fit, by failing to recognize that monotonic transformations can affect results, by failing to realize that a complete analysis of variance decomposition can perfectly account for any set of data, by failing to realize that correlation coefficients can be misleading, by failing to recognize that people often respond configurally to information in sentences, and by committing various other foolish or careless errors. Anderson also suggests that all would have been fine if only Gollob and his colleagues had used Anderson's preferred methods to guide their data collection and analyses.

The present reply argues that all of Anderson's major criticisms of the S–V–O model are either wrong, irrelevant, or misleading. Since Anderson's criticisms focus primarily on

Work on this article was supported by National Science Foundation Grant SOC75-13303.

I wish to thank Robert S. Wyer, Jr., Robyn M. Dawes, Betty B. Rossman, and Robert M. McFatter for their extremely helpful comments on a draft on this article. Additionally, I thank Kenneth Purcell and Maureen Gollob for helpful discussions concerning the postscript.

Gollob's work, this reply emphasizes comparisons of Gollob's (1974a, 1974b; Rossman & Gollob, 1976) claims and practices with those attributed to him by Anderson. Although the specific content of the reply is concerned with the S–V–O model, much of the discussion is relevant to issues of general importance to investigators who use analysis of variance models or other relatively simple mathematical models in their work.

Anderson's critique frequently ignores the necessity of considering the theoretical and psychological meaningfulness of a model in evaluating its usefulness. To enable meaningfulness to be given adequate consideration, the present article summarizes the major characteristics of the S–V–O model before giving detailed consideration to Anderson's criticisms. In typical applications of the S–V–O approach, considerations of judges' phenomenology play a crucial role, but since most of Anderson's criticisms are primarily technical in nature, the following description emphasizes technical aspects of the model.

The S–V–O Approach to Social Cognition

It should be noted at the outset that although the historical links between balance theory and the S–V–O approach to social cognition are strong, the similarity between the two systems is much weaker than Anderson implies by his decision to refer to the S–V–O model as the "balance triad model." The S–V–O approach differs from balance theory in several ways: The S–V–O approach considers six cognitive biases in addition to Heiderian balance and proposes a framework within which the joint effects of the hypothesized biases can be investigated; it deals with stimuli expressed as subject–verb–object sentences rather than as triads; it emphasizes that the relative importance of cognitive biases in an item set will vary greatly depending on the specific content of the item set and on the type of inference (or other judgment) being made; it focuses on the role of informational processes in affecting social judgments; and it makes several theoretical claims that are not part of traditional balance theory.

The S–V–O approach to social cognition provides a systematic method of investigating and conceptualizing several social cognition problems within the context of subject–verb–object sentences such as "Friendly Bill dislikes criminals" or "Intelligent men oppose antiobscenity laws." The substantive examples Anderson uses in his critique involve social inferences made on the basis of information that is highly evaluative in nature. Therefore, in order to facilitate discussion, I shall summarize only those aspects of the S–V–O approach that are relevant when dealing with item sets in which social inference judgments are obtained, and in which each of the sentence components is described either by a positively evaluated term (+1) or by a negatively evaluated term (−1).

Although Anderson considers only verb inferences, the S–V–O model distinguishes between three major types of social inference judgment: subject inferences, verb inferences, and object inferences. When making verb inferences a perceiver judges the probability that an actor with specified characteristics behaves or feels in a particular way toward a recipient who also has some specified characteristics—for example, "How likely is it that the kind man hates Mr. B who is a psychologist?" Examples of subject and object inferences, respectively, are "The man hates Mr. B who is a psychologist. How likely is it that the man is kind?" and "The kind man hates Mr. B. How likely is it that Mr. B is a psychologist?"

To apply the S–V–O approach, *item sets* are constructed in which two sentence subjects, two verbs, and two objects are factorially combined to yield the eight basic sentence types shown in Table 1. For example, the code "+ + −" represents the sentence type in which the subject and the verb are positively evaluated and the object is negatively evaluated. As shown in Table 1, each of the eight sentence types can be described according to the presence or absence of seven different cognitive biases—in the case of evaluative content there are three positivity biases and four balance biases. The presence or absence of each cognitive bias is easily determined. Let S′, V′, and O′, respectively, denote the sign of the sentence subject, verb, and object. Then, whenever S′, V′, or O′ is

positive, or the product S'V', S'O', V'O', or S'V'O' is positive, the specified sentence type is said to possess the corresponding cognitive bias. The names of the seven biases correspond to the names of the seven sources of variation one would have in a Subject × Verb × Object analysis of variance.

I shall now briefly discuss interpretations of the seven cognitive biases that often seem appropriate when dealing with evaluative content that is relevant to interpersonal relationships. S, V, and O positivity are cognitive biases that should be important in affecting inferences to the extent that judges tend to assume that, on the average, an actor, behavior, or object will have positively evaluated characteristics rather than negatively evaluated characteristics. It is hypothesized that SV balance will be important in affecting an inference to the extent that the perceiver expects the sentence subject and verb to have the same evaluative sign regardless of the characteristics of the recipient of the act (e.g., perceivers expect good people to do good things and bad people to do bad things). Similar lines of reasoning are used to relate SO balance and VO balance to relevant aspects of perceivers' phenomenology. SVO balance is simply traditional Heiderian balance. For more detailed discussion of the psychological significance of the biases in both evaluative and nonevaluative cases, see Gollob (1974b, pp. 288–292, 316–319).

In the S–V–O approach, each of the cognitive biases is thought of as providing a psychologically meaningful unit of information that is combined with other biases to yield a likelihood judgment. Formally, the most general version of the model assumes that the likelihood judgment, y_i, associated with the ith sentence type in an item set is given by the equation

$$y_i = \sum_{j=1}^{7} w_j B_{ij} + \text{constant}, \qquad (1)$$

where B_{ij} is equal to $+1$ or -1, depending on whether the jth cognitive bias is present or absent in the ith sentence in the item set, and w_j is the weight given to the jth cognitive bias for the item set (Gollob, 1974b, p. 292). The absolute value of the weight assigned to a bias reflects the importance of the bias in describing the inferences in the item set.

Table 1
Presence (+1) and Absence (−1) of Cognitive Biases in Each Sentence Type

Sentence type	Positivity			Balance			
	S	V	O	SV	SO	VO	SVO
+ + +	1	1	1	1	1	1	1
+ + −	1	1	−1	1	−1	−1	−1
+ − +	1	−1	1	−1	1	−1	−1
+ − −	1	−1	−1	−1	−1	1	1
− + +	−1	1	1	−1	−1	1	−1
− + −	−1	1	−1	−1	1	−1	1
− − +	−1	−1	1	1	−1	−1	1
− − −	−1	−1	−1	1	1	1	−1

Note. S = subject, V = verb, O = object.

When no restrictions are placed on the weights, Equation 1 is simply one way of writing the standard analysis of variance decomposition for a $2 \times 2 \times 2$ table. Significance tests of corresponding sources of variation in an analysis of variance are tests of the significance of the regression weights in Equation 1. In order to give the model some predictive power, some restrictions must be placed on the weights. The major restrictions discussed by Gollob (1974b, pp. 292–295) are summarized in the following section.

Weight Restrictions for the S–V–O Model

Nonnegative weight hypothesis. This hypothesis states that any cognitive bias useful in describing the judgment will be given a positive weight. The interpretations given above for the biases implicitly assumed that this hypothesis will hold when dealing with evaluative content.

Negatively accelerated weight hypothesis. This hypothesis states that when the absolute values of the weights in Equation 1 are put in rank order from largest to smallest, the size of the nonzero weights decreases at a slower and slower rate (Gollob, 1974b, p. 295; Rossman & Gollob, 1976, p. 377). Empirical results suggest that this negatively accelerated curve usually is fairly steep, so that typically only two or three cognitive biases

in a particular item set are given substantial weights (Gollob, 1974b; Rossman & Gollob, 1976; Wyer, 1974).

Relevant-bias hypothesis. This hypothesis states that the three cognitive biases that do not involve the sentence component to be inferred will be given zero weights. For example, in the case of verb inferences the hypothesis states that S positivity, O positivity, and SO balance will be given weights of zero, and that only V positivity and SV, VO, and SVO balance can be relevant in accounting for verb inferences. The relevant-bias hypothesis is expected to apply in most evaluative item sets in which each of the sentence components is described in terms of bipolar opposites (e.g., friendly–unfriendly, likes–dislikes, supports–opposes, liberals–conservatives). Use of such bipolar opposites, however, does not ensure that the relevant-bias hypothesis will hold (see Gollob, 1974b, pp. 294, 318–319).

Some intuitive feeling for the psychological meaningfulness of the relevant-bias hypothesis may be gained by considering an example. In making a verb inference, values along the verb dimension (e.g., helps–harms) often have implications for the judgment, both when they are considered alone and when they are considered in conjunction with other sentence components. More specifically, to the extent that a judge feels that it is generally true that people help rather than hurt others, V positivity should contribute to his or her inference; to the extent that he or she believes that the evaluative characteristics of the actor (i.e., the sentence subject) affect the likelihood of the actor helping another person, SV balance should contribute; to the extent that he or she believes that the evaluative characteristics of the recipient (i.e., the sentence object) affect the likelihood that the recipient will be helped, VO balance should contribute; finally, to the extent that the evaluative characteristics of both the sentence subject and object are jointly considered, SVO balance should contribute.

When the nonnegative weight hypothesis, the negatively accelerated weight hypothesis, and the relevant-bias hypothesis all hold, a different special case of the general S–V–O model is obtained for subject, verb, and object inferences. Gollob (1974b) has shown that each of these submodels implies that only 24 different orderings of the eight basic sentence types can be obtained in data. Since there are 40,320 possible orderings of the eight sentence types, it is clear that these special cases of the general model have considerable predictive power.

Other weight restrictions. In addition to the above hypotheses, which have rather broad applicability to social inference item sets, it is of course possible to use additional theoretical and intuitive considerations to make more specific a priori predictions concerning the relative importance of the biases. Such considerations depend on the content of the item sets, the experimental manipulations used, the characteristics of the judges, and the types of judgments obtained. For example, since the phenomenological basis for the relevant-bias hypothesis is applicable only to inference judgments, Rossman and Gollob (1976, pp. 379–380) did not use this hypothesis to make predictions concerning pleasantness judgments. Instead they used the nonnegative weight hypothesis and various theoretical and empirical considerations of subjects' phenomenology to predict that VO and SVO balance would dominate pleasantness judgments and would be given positive weights. The resulting special case of the general model was reasonably well supported by the data. In general, most S–V–O research to date has involved testing various special cases of the general model given by Equation 1.

Having reviewed the main ideas in the S–V–O formulation, let us now consider the specific issues Anderson raises in his critique.

Technical Issues

Most of Anderson's technical criticisms of the S–V–O work of Gollob and his colleagues are based on issues concerned with tests of goodness of fit.

Testing Goodness of Fit

Can the S–V–O model fit data perfectly? Anderson (1977) begins his formal criticism of the S–V–O model with the comment: "An

odd difficulty faces the user of the balance triad [S–V–O] model: It can always fit the data perfectly. As is well known, the complete analysis of variance model holds by statistical definition and so is not in general a model of substantive process" (p. 142). Proceeding from this base, Anderson repeatedly claims that the S–V–O model has no way of testing goodness of fit and therefore is defenseless against various types of measurement problems. These claims are wrong because most S–V–O work by Gollob, Wyer, and their co-workers has investigated special cases of the complete analysis of variance model, for which appropriate goodness-of-fit tests are available. Incidentally, the methods of analysis typically advocated by Anderson also involve testing special cases of the complete analysis of variance model.

Gollob (1974b, pp. 293–301) spends eight pages discussing plausible restrictions that can be placed on the weights in the complete S–V–O model. Moreover, most of the empirical results reported in Gollob (1974a, 1974b) were directed toward testing special cases of the model that resulted when various combinations of the nonnegative weight, negatively accelerated weight, and relevant-bias hypotheses were used to restrict the parameters of the general model. Other intuitive and theoretical considerations concerning subjects' phenomenology also have been used to make a priori predictions concerning the relative importance of biases in different item sets and under different experimental manipulations (e.g., Rossman & Gollob, 1976; Wyer, 1974, 1975; Wyer, Henninger, & Wolfson, 1975). Each different set of predictions yielded a different special case of the model, which was not forced to fit the data perfectly. Since Anderson (1977, p. 146) explicitly acknowledges that special cases of the complete model can readily be tested, it is clearly misleading for him to ignore the fact that it is precisely such special cases of the complete model that have been the focus of most S–V–O research done to date.

In addition to making the misleading claim that the S–V–O model can always fit data perfectly, Anderson misrepresents the specific methods that Gollob and his colleagues actually have used to assess the goodness of fit of the S–V–O model.

Specific tests of goodness of fit used in S–V–O research. In this section I shall briefly describe several published analyses that were specifically designed to assess the goodness of fit of various special cases of the complete S–V–O model. In discussing the verb inference submodel, Gollob (1974a, pp. 162–163, 165, 167–168; 1974b, p. 304) presented several figures that compared obtained mean ratings with the best fitting predicted order of the mean ratings. These figures showed all occurrences of errors in the predicted order and indicated whether or not each error was statistically significant. This enabled discrepancies from prediction to be examined in detail. These are precisely the kinds of goodness-of-fit tests that Anderson (1977, pp. 145–146) claims are missing from evaluations of the S–V–O model.

Other methods of evaluating goodness of fit also have been used in S–V–O research. Gollob (1974a, pp. 170–171) and Rossman and Gollob (1976, pp. 382–385) presented clearly labeled sections that discussed several analyses explicitly directed toward evaluating the degree to which various hypotheses concerning the general S–V–O model held; failures of the hypotheses to hold would help to identify specific aspects of lack of fit of the associated special cases of the model. In particular, both of these papers reported indices of the magnitude and/or statistical significance of the data's discrepancies from the patterns predicted by the relevant-bias hypothesis, the nonnegative weight hypothesis, and the negatively accelerated weight (or a closely related) hypothesis. Wyer (1975) and Wyer, Henninger, and Wolfson (1975) also have used appropriate methods to test the statistical significance of sources of variation attributable to biases that they predicted would be unimportant in accounting for their data.

Although there are some exceptions (cf. Gollob, 1974b, pp. 294, 318–319), the overall results of the above tests of goodness of fit provide strong support for various special cases of the model that were investigated. The following section rebuts Anderson's

Table 2
S–V–O Weights for Anderson's Item Sets A and C

Bias	Item Set A (helps/harms) Weight	%	Item Set C (helps/hinders) Weight	%
S	−.92	4	−.03	0
V	1.30	9	.12	0
O	.39	1	−.11	0
SV	3.70	71	2.50	59
SO	.79	3	.07	0
VO	1.09	6	.78	6
SVO	1.05	6	1.94	35

Note. S = subject; V = verb; O = object. The weights were taken from Anderson's (1977, p. 149) Table 2. Figures in the columns labeled "%" give the percentage of variation in the item set that is accounted for by each bias. In both item sets the levels for the sentence subject are *kind/cruel* and the levels for the object are *physicians/criminals*.

(1977) criticisms of Gollob's use of correlationlike indices.

Appropriate uses of correlationlike indices in S–V–O research. Anderson belabors the well-known fact that correlations between model predictions and data can be extremely high even when the model is seriously in error. He then, without presenting specific examples or any qualifying conditions, uses this innocuous premise as the basis for various criticisms concerning Gollob's use of correlation coefficients, percentages of variation, and other correlationlike indices. Anderson's criticisms include such sweeping statements as "Clearly, correlations can be extremely misleading in model analysis, for they obscure and misrepresent the facts . . . . The correlation coefficient and similar statistics are not valid as tests of fit . . . . The not infrequent practice of comparing several models in terms of correlations simply compounds the problem" (1977, pp. 145–146). So strong is his damnation of correlations that Anderson does not give even a hint that correlations have appropriate, as well as inappropriate, uses in model analysis.

We will now use the results of S–V–O analyses presented by Anderson (1977, p. 149) to illustrate the major uses that Gollob (1974a, 1974b; Rossman & Gollob, 1976) has made of correlationlike indices in working with the S–V–O model. The data are presented in Table 2, but the descriptions of the specific item content are deferred to a point in the discussion where they are more relevant. For convenience, the following discussion assumes that the percentages being compared are significantly different from each other.

In one or more of the papers cited above, Gollob has made statements analogous to the following: (a) In Anderson's Item Sets A and C, respectively, SVO balance accounts for 6% and 35% of the item-set variation, therefore SVO balance is relatively more important in accounting for variation in Item Set C than in Item Set A. (b) In Anderson's Item Set A, SV balance and SVO balance, respectively, account for 71% and 6% of the item-set variation, therefore SV balance is relatively more important than SVO balance in accounting for variation in Item Set A. (c) The S–V–O verb inference submodel accounts for 92% of the variation in Anderson's Item Set A and for 98% of the variation in his Item Set C, therefore the verb inference submodel is more effective in accounting for variation in Item Set C than in Item Set A. These are appropriate uses of percentage of variation indices; they provide useful summary descriptions of various aspects of the data.

Finally, Anderson (1977) asserts that the common practice of comparing several models in terms of correlations or percentages of variation is not a valid procedure. For a counterexample to Anderson's assertion, consider the fact that the verb inference submodel and the object inference submodel account for 92% and 6%, respectively, of the variation in Anderson's Item Set A. Assuming the verb inference submodel is at least as psychologically meaningful as the object inference submodel, surely these data provide legitimate grounds for concluding that the verb inference submodel provides a better account of the data than does its competitor.

Goodness of fit is not enough. Although no evaluation of a model can be complete without considering the results of detailed tests of goodness of fit, more is needed. In general, it is necessary to evaluate not only

discrepancies from the fit of the model, but also to evaluate the fit itself. Knowledge that there are no reliable or important deviations from a model's fit does not imply that the model is useful in accounting for the data. One typically also wants to know how well the model accounts for the data and whether it accounts for a statistically significant amount of variation. Moreover, contrary to the flavor of Anderson's remarks, it is not enough to consider only statistical tests in evaluating the fit of a model. It is also necessary to consider the psychological meaningfulness of the values obtained for the model's parameters. Work using the S–V–O approach has been encouraging in this regard.

Summary. In summary, all of Anderson's claims concerning methods Gollob has used to test goodness of fit can be refuted. In particular, Gollob's S–V–O articles have focused on studying special cases of the model, which need not fit the data perfectly; appropriate techniques have been used to test the goodness of fit of these special cases; and correlationlike indices have been used appropriately to provide useful summaries of various aspects of the model's relation to data. Let us now discuss scaling issues—the second major category of technical issues that Anderson raises.

The Importance of Using Appropriate Scales

The need for interval response scales. Anderson uses a set of fictitious S–V–O data to illustrate that a perfect additive fit can be destroyed by moving a single point, and that when this is done in a $2 \times 2 \times 2$ design all four interactions, which were initially zero, are changed to have the same nonzero value. He correctly points out that in this instance it would make little sense to interpret the four interactions as indicating that four distinct balance tendencies were operating. He makes the traditional suggestion that it would be more parsimonious to interpret the interactions as resulting from an aberrant response, and in this example the aberrant response could well be the result of a floor effect. Anderson's (1977, p. 143) general argument is that scaling difficulties can cause observed interactions to contain undecipherable confoundings, and that the S–V–O model has no way to guard against such confoundings because it lacks a test of goodness of fit. Let us now examine some of the details of his argument.

It is argued above that in spite of Anderson's claim to the contrary, the S–V–O model does have tests of goodness of fit. For example, a simple test shows that the fictitious verb inference data that Anderson (1977, pp. 142–143) uses to illustrate a floor effect cannot be fit adequately by the S–V–O submodel for verb inferences. In this application the relevant-bias hypothesis predicts that the S, O, and SO sources of variation will be unimportant. In fact, however, these sources account for over 70% of the variation in Anderson's example, and the submodel obviously fails to meet the goodness-of-fit test. Consequently, the S–V–O model would not be expected to be helpful in deciphering the meaning of the observed interactions; other interpretations would be sought—including, of course, interpretations that allow for the possibility of scaling artifacts.[1]

Anderson is correct in pointing out that rating scales are subject to biases which can make it risky to give substantive interpretations to main effects and/or interactions. Fortunately, he also is correct when he later points out that "relatively modest experimental precautions, such as the use of stimulus end anchors, can largely eliminate these biases in many experimental situations" (1977, p. 144). Gollob and Wyer agree and have consistently used such precautions in their research.

Although a floor effect or other artifact can parsimoniously account for Anderson's single set of fictitious data, it seems highly unlikely that scaling artifacts can explain the

[1] Examples of content-based interpretations of some verb inference item sets in which the relevant-bias hypothesis was severely disconfirmed were given by Gollob (1974b, pp. 318–319). These examples involved item sets whose sentence subjects and objects were nonevaluative. Such severe disconfirmations of the relevant-bias hypothesis have rarely been observed in item sets whose sentence components are bipolar and primarily evaluative in content (but for a probable exception see Gollob, 1974b, p. 294).

results that have been observed in the many S–V–O item sets studied by Gollob, Wyer, and their co-workers. In fact, Anderson makes no effort to apply "scaling artifact" interpretations to even a single set of actual data.

In summary, it is agreed that measurement issues must be considered when any model is used to help understand psychological data. By using appropriate experimental precautions to guard against scale artifacts, by treating rating-scale data as though they are interval data, and by assessing the goodness of fit of special cases of the model, Gollob, Wyer, and their co-workers have repeatedly obtained psychologically meaningful results within the S–V–O framework.

The need for ratio stimulus scales. In Anderson's section on "The Need for Ratio Stimulus Scales," he points out that the areas of a set of rectangles can be represented (a) as the product of Base × Height or (b) by an analysis of variance decomposition that expresses the area of each rectangle as the sum of a grand mean, two main effects, and an interaction. He also points out that an analogous situation exists for the volume of rectangular solids. Anderson argues that the analysis of variance decomposition, if taken literally, would imply that the area and/or volume is the sum of several independent processes, and that the main effects and interactions in the analysis of variance decomposition are terms "whose meaning is essentially artificial. . . . These examples, of course, depend on the assumption that the true integration rule is multiplicative in the two or three variables. . . . Thus, the problem of stimulus zeros seems to be relevant to at least some applications of the balance triad model" (1977, p. 145).

Anderson seems casual about assuming which of two mathematically equivalent models describes "the true integration rule." Rather than choosing between two mathematically equivalent models on the basis of an assumption that one knows "the true integration rule," it probably is more reasonable to ask which of the two models is more helpful to use in thinking about the problems of interest. In the case of Anderson's rectangles, it is obvious that the multiplicative model is more helpful. In the case of S–V–O item sets, on the other hand, the multiplicative model discussed by Anderson rarely provides a reasonable alternative to the S–V–O model. For example, using conjoint-measurement techniques (Krantz & Tversky, 1971, pp. 160–163), it can be shown that even if one allows arbitrary monotonic transformations of the response scales, it is impossible for a multiplicative model to account for the data in even one of the six S–V–O item sets Anderson presents in his Table 1 (1977, p. 148).[2] More important, except when grossly implausible restrictions are met, the three-way multiplicative model and the relevant-bias hypothesis are inconsistent with each other. For example, in the case of verb inferences, the relevant-bias hypothesis implies that S, O, and SO sources of variation are all equal to zero. Except in trivial cases, the resulting S–V–O submodel for verb inferences and the three-way multiplicative model can both be correct if, and only if, $w_{svo} \neq 0$ and $w_v w_{svo} = w_{sv} w_{vo}$.[3] These conditions imply that SVO

[2] In order for a multiplicative rule to fit the data in an S–V–O item set, it is necessary that the ordering for the four combinations of S and V either be the same or be exactly reversed for the two levels of O. Similar relations must hold for the ordering of the four combinations of S and O at each level of V, and for the four combinations of V and O at each level of S. None of Anderson's item sets satisfies these necessary conditions; many of the failures are substantial and seem unlikely to be due to error in the data.

[3] This footnote shows that the claim made in the text is correct. If the multiplicative model holds, we have

$$y_{ijk} = S_i V_j O_k + \text{constant},$$

where y_{ijk} is the likelihood judgment of the ijkth sentence in the item set, and where i, j and k each are either positive or negative. Thus, y_{+-+} denotes the sentence with a positive subject, negative verb, and positive object. S_+ and S_-, respectively, refer to the scale values for the positive and negative sentence subject, and V_+, V_-, O_+, and O_- are analogously defined. In order to avoid trivial cases of the multiplicative model we assume that $S_+ \neq S_-$, $V_+ \neq V_-$, and $O_+ \neq O_-$, that is, we assume that the positive and negative scale values for any given sentence component are not equal to each other.

The weight for an S–V–O bias is equal to half the difference between the mean of the four sentences that have the bias and the mean of the four sen-

balance can never have a weight of zero. Moreover, if SV balance and/or VO balance have a weight of zero, then V positivity must also have a weight of zero, and vice versa. Since these highly restrictive and psychologically vacuous conditions are rarely met, the multiplicative model usually cannot account for the data obtained in the many studies that have found strong support for the relevant-bias hypothesis (Gollob, 1974a, 1974b; Rossman & Gollob, 1976; Wyer, 1974, 1975; Wyer, Henninger, & Wolfson, 1975). Moreover, since we seek parsimonious understanding of many sets of data—not merely of isolated cases—the S–V–O representation usually would be preferable even in those rare cases where the multiplicative model could adequately describe the data.

---

tences that do not have the bias. Thus, when the multiplicative model holds, the S positivity weight can be expressed as

$$w_s = (y_{+..} - y_{-..})/2 = (S_+V_.O_. - S_-V_.O_.)/2 = V_.O_.(S_+ - S_-)/2,$$

where a dot replacing a subscript indicates that a mean has been computed over the levels of the replaced subscript. When similar calculations are done for w_o and w_{so}, we obtain

$$w_o = S_.V_.(O_+ - O_-)/2$$

$$w_{so} = V_.(S_+ - S_-)(O_+ - O_-)/4.$$

Since $S_+ \neq S_-$ and $O_+ \neq O_-$, we see that the verb inference submodel that assumes $w_s = w_o = w_{so} = 0$ can hold if, and only if, $V_. = 0$. Proceeding as we did for w_s, and using the fact that $V_. = 0$ implies that $V_- = -V_+$, we obtain the following expressions for the weights for V positivity, SV, VO, and SVO balance:

$$w_v = S_.O_.V_+$$

$$w_{sv} = O_.V_+(S_+ - S_-)$$

$$w_{vo} = S_.V_+(O_+ - O_-)$$

$$w_{svo} = V_+(S_+ - S_-)(O_+ - O_-).$$

Since $V_+ = -V_-$ and $V_+ \neq V_-$, we see that $V_+ \neq 0$, and therefore the equation for w_{svo} implies that the weight for SVO balance can never be zero. It is easy to verify that the above equations for the weights also imply that $w_v w_{svo} = w_{sv} w_{vo}$. Thus, if these conditions are not met, then the multiplicative model and the S–V–O submodel for verb inferences cannot both be correct. Similar conclusions hold for the subject inference and object inference submodels.

Summary

Anderson, of course, is correct in asserting that measurement issues and tests of goodness of fit must be considered when evaluating models that are intended to help us understand psychological data. The above discussion demonstrates that contrary to the charges Anderson makes in his critique, Gollob and his colleagues have dealt with these matters in careful, effective, and responsible ways. The technical portion of Anderson's critique, however, ignores the fact that no matter how sound one's measurement methods or how well one's model fits some data, it is necessary to consider the question of whether the model makes sense. Surely an investigator oriented toward using models that make good psychological sense would not seriously suggest using an analysis of variance decomposition to analyze areas of rectangles! For a model to be most useful, the values obtained for its parameters should have sensible interpretations in terms of our best understanding of the psychological processes involved. In the case of the S–V–O model, it has been found repeatedly that substantive interpretations of the weights given to the hypothesized cognitive biases make good psychological sense. At this point it is natural to consider Anderson's criticisms concerning substantive issues.

Substantive Issues

Configurality

Anderson's position concerning ways in which the S–V–O model is affected by configural response patterns is based on a misunderstanding of how weights in the S–V–O model should be interpreted. For this reason, I shall first discuss correct methods of interpreting the weights in S–V–O analyses, and shall then discuss ways that the S–V–O model deals with configural response patterns.

Interpretation of weights in S–V–O analyses. Anderson considers the possibility that the weights in an S–V–O analysis can be interpreted as estimates of the weights of biases in *individual sentences*. He concludes

that this interpretation makes no sense. Gollob and Wyer agree, and they neither made nor intended this interpretation. Although the S–V–O model assumes that the judgment of a given sentence is a linear combination of the various psychological biases, the S–V–O method of analysis does not yield direct estimates of the weights for that linear combination. Gollob (1974b, p. 292) and Wyer (1974) emphasize that the weights obtained in an S–V–O analysis are interpreted as reflecting the direction and importance of biases in accounting for variation *within individual item sets*—not within individual sentences. To compare Gollob's interpretation of the weights obtained in an S–V–O analysis with the interpretation attributed to him by Anderson, let us consider the results of S–V–O analyses of Anderson's Item Sets A and C, which are presented in Table 2.

The data for Anderson's Item Set A consist of college students' responses to eight sentences of the following form: "Bill is *kind* (*cruel*); how probable is it that Bill *helps* (*harms*) *physicians* (*criminals*)?" The italicized words denote evaluatively positive (negative) levels of the sentence subject, verb, and object, respectively. Responses were made orally using a 0–20 rating scale whose ends were defined by the terms *extremely improbable* and *extremely probable*. Anderson's Item Set C was based on responses to eight sentences that were the same as those in Item Set A except that the verb *hinders* was substituted for the verb *harms*. Thus, the four sentences that contain the verb *helps* are common to both item sets.

Anderson reminds the reader that the ratings associated with each sentence in each item set can be recovered by applying the weights in Table 2 to the contrasts that define the biases (see Table 1) and emphasizes that there are large and statistically significant differences in the patterns of weights in the two item sets. On the basis of this observation, he correctly points out that each of the four sentences common to Item Sets A and C (i.e., the sentences that contain the verb *helps*) have two distinct representations, one in Item Set A and one in Item Set C. He then argues that there is no way to choose between these two representations and from this draws the conclusion that the S–V–O method of analysis "would seem to have no use" (1977, p. 149). The confusion here seems to stem from Anderson's failure to recognize that the two different representations are not inconsistent with each other, and therefore it is not necessary to choose between them—both can be correct. The weights obtained in the S–V–O analysis of the two item sets express the four common sentences in terms that are *relative* to the other content in each item set. Thus, in Item Set A, the four sentences that contain the verb *helps* are expressed in terms relative to the four sentences that contain the verb *harms*, whereas in Item Set C, they are expressed in terms relative to the four sentences that contain the verb *hinders*. Obviously the results of an analysis of variance are changed when the data input to it are changed. Since the issue of how to interpret the weights in an S–V–O analysis is at the core of the matter, the following paragraphs discuss interpretation of the weights in detail.

To illustrate the relativistic interpretation of the weights obtained in an S–V–O analysis, let us consider the results Anderson obtained for verb positivity. In Item Set A, verb positivity was given a weight of 1.30, and in Item Set C it was given a weight of .12. Using correct methods of interpretation, one would view the different weights given to verb positivity in Item Sets A and C as indicating that for the particular sentence subjects and objects used, verb positivity is more important in accounting for verb inferences when the verbs are *helps* and *harms* (Item Set A) than when the verbs are *helps* and *hinders* (Item Set C). That is, on the average, the tendency for judges to infer that a person will help rather than harm, regardless of whether the person is described as kind or cruel, and regardless of whether the object is physicians or criminals, is stronger than the comparable tendency for judges to infer that a person will help rather than hinder.

Further insight into the meaning of the weights obtained in an S–V–O analysis can be gained by recalling that the analysis of variance contrast that defines a particular

bias assigns +1 values to the sentences that have the bias and assigns −1 values to the sentences that do not have the bias. Thus, the weight for a bias is closely related to the difference between the mean of the four sentences that have the bias and the mean of the four sentences that do not have the bias. Specifically, the weight given to a bias is equal to half the difference between these two means. In his uses of the S–V–O model, Wyer does not report the S–V–O weights per se; instead, he reports the difference between the mean rating of the sentences having the bias and that of the sentences not having the bias in question. Let us now use this perspective to look once again at the difference between the verb positivity weights in Anderson's Item Sets A and C. The mean rating of the four sentences containing the verb *helps* was 9.94 for Set A and 9.49 for Set C. (Since the same four sentences were used in both item sets, probably the difference between these two means is due to measurement error.) The mean rating given to the sentences that used the verb *harms* was 7.34, whereas that for the four sentences that used the verb *hinders* was 9.25. Thus, as one would expect, the average judged probability that kind or cruel people will harm physicians or criminals is considerably less than the average judged probability that kind or cruel people will hinder physicians or criminals. The difference between the weights for verb positivity in the two item sets reflects these characteristics of the data. Thus, the weight for verb positivity in Set A was $(9.94 - 7.34)/2 = 1.30$, and the weight in Set C was $(9.49 - 9.25)/2 = .12$.

In a less technical way, let us now consider interpretation of Anderson's results concerning SV and SVO balance in the two item sets. Suppose that the tendency among judges to think that a person who harms someone is bad is much stronger than their corresponding tendency to think that a person who hinders someone is bad, that is, the evaluative implications of hindering someone depend to a much greater extent on the characteristics of the person who is hindered. This phenomenological assumption would lead SV balance to contribute more to judgments in the *help/harm* item set, and because SVO balance allows for the importance of the characteristics of the object, the assumption would lead SVO balance to be more important in the *help/hinder* item set. As shown in Table 2, this is what occurred in Anderson's data. Thus, when interpreted correctly, findings that Anderson emphasizes as invalidating the S–V–O model are seen in reality to be amenable to a psychologically plausible interpretation in terms of the model.

Having shown that Anderson's position is based on an incorrect interpretation of the weights in S–V–O analyses, and having discussed correct methods of interpreting the weights, I shall now discuss more specifically the question of how the S–V–O model deals with configural responding.

Configural effects and the S–V–O model. As an example of a configural response, Anderson emphasizes that with respect to verb inference judgments, the difference between harming and hindering physicians is much less than the difference between harming and hindering criminals. The judged likelihood of the verb depends in part on the object. Anderson's discussion conveys the incorrect impression that S–V–O researchers have not been concerned with such configural effects. Gollob and Wyer have discussed dozens of S–V–O analyses of item sets that involve highly configural responses. For example, Item Sets 1 and 4 in Gollob's (1974a, p. 165) Table 2 include data showing that with respect to verb inference judgments, the difference between helping and admiring friendly people is much less than the difference between helping and admiring unfriendly people. His subjects inferred that a friendly person was reasonably likely to help both friendly and unfriendly people, but they inferred that admiration was considerably more likely to be directed toward friendly, rather than unfriendly, people. This help–admire example closely parallels Anderson's harm–hinder example of configural responding. Gollob (1974a, pp. 166–168; 1974b, p. 303) grouped together several item sets with configural patterns similar to the help–admire example and found that the hypothesized cognitive biases of the S–V–O model were helpful in thinking about the results.

In general, since the S–V–O model and its hypothesized cognitive biases are psychologically meaningful and can account for highly configural data such as those presented by Anderson, it follows that configural responding poses no special problems for the formulation. The model simply conceptualizes configural responding in terms of the effect such responding has on the relative importance of the hypothesized cognitive biases of the model.

We have seen that the S–V–O system can handle configurality issues of the type raised by Anderson. There also is another sense in which the S–V–O system is intimately concerned with configural aspects of judges' responses. The S–V–O conceptualization recognizes that a given piece of information can contribute to judgments simultaneously in a variety of ways, and a basic assumption of the model is that judges often use configurations of information (combinations of S, V, and O) as single informational units. In the present article, these informational units are referred to as cognitive biases; Wyer often refers to them as informational cues. At one level, the fact that notions of configurality are essential in defining the hypothesized biases is one reason that nonconfigural models, such as the multiplying model advocated by Anderson, typically are unable to account for data that can be conveniently conceptualized in terms of the S–V–O model (see Footnotes 2 and 3).

In summary, if one is to obtain sensible interpretations of the weights obtained in S–V–O analyses, one must interpret them in the context of the item sets from which they are obtained. When this is done, configural response patterns pose no special problem, and the weights often can be used to compare the contributions of hypothesized biases across different item sets in a systematic and psychologically meaningful way.

Nonadditivity

Anderson argues that if the hypothesized S–V–O biases are psychologically real, they probably are combined by an averaging, rather than an adding, rule. The basic argument Anderson presents in support of his position is that because the averaging rule has worked well in numerous investigations, it probably also would work well if applied to cognitive biases. The question is one that can be investigated empirically, and there seems to be little value in engaging in further speculation on the issue. It is important, however, to realize that the ratio of the weight of one bias to another is the same regardless of whether the biases are combined in accordance with an additive or with a simple weighted-average rule. Thus, the "adding versus averaging" question raised by Anderson is irrelevant if one's objective is to compare the *relative* importance of the hypothesized biases in affecting judgments.

An Alternative Approach

Anderson's (1977) section entitled "An Alternative Approach" presents (a) an alternative approach for the analysis of S–V–O item sets, (b) a criticism of a procedure Gollob (1974b, pp. 305–306, 313–316) used to transform 2×2 item sets to make them amenable to S–V–O analyses, (c) a multiplicative model that is sometimes useful in the analysis of verb inference data when sentences are constructed by using one verb in combination with several levels of sentence subject and object, and (d) a set of general arguments advocating use of simple algebraic models to study problems in implicit personality theory. I shall consider each of these topics in turn.

Anderson's Method for Analyzing S–V–O Item Sets

In his subsection entitled "A Multiplying Model for Subject–Object Integration" (1977, pp. 151–153), Anderson implicitly advises that one should avoid collecting data in the $2 \times 2 \times 2$ form of an S–V–O item set. If, however, one ends up with verb inference data in this form, he recommends that the S–V–O item sets be investigated as two separate 2×2 designs—one for each of the two verbs. He recommends that each of the 2×2 designs be conceptualized and analyzed in terms of a multiplicative model

that states that the judged likelihood of the verb can be expressed as the product of a number assigned to the sentence subject and a number assigned to the sentence object. He then says that "the 2×2 design does not provide a proper test of goodness of fit for the multiplying model" (p. 153), and he goes on to argue that a better test of the multiplying model can be obtained by quantifying the subject and object term (see his Figure 3, p. 151).

Anderson's comment highlights a limitation of using the procedure he recommends for the analysis of S–V–O item sets. The limitation, however, does not apply to S–V–O analyses of intact $2 \times 2 \times 2$ item sets because, as was emphasized above, appropriate tests of goodness of fit are possible and have been used routinely in S–V–O research. Moreover, the S–V–O model enables one to conceptualize the data in an intact item set in terms of the hypothesized cognitive biases, whereas the analysis method proposed by Anderson breaks the design into two separate pieces and provides no natural way of integrating the results of the two analyses. In addition, the S–V–O model is used not only in the investigation of verb inferences, which are discussed by Anderson, but also in the investigation of subject inferences, object inferences, pleasantness, and other types of social judgments.

Transforming 2×2 Analyses into Equivalent $2 \times 2 \times 2$ Analyses

Anderson (1977, pp. 152–153) uses the terms "artificial," "misleading," and "awkward" to describe a procedure Gollob (1974b, pp. 305, 313) used to enable Rodrigues's (1968) verb inference data and Osgood and Tannenbaum's (1955) subject and object inference data to be analyzed using the S–V–O model. The procedure involved transforming two-way analyses into *equivalent* three-way analyses. Rodrigues's verb inference data will be used to describe the procedure and the reasoning that motivated its use; generalization of the procedure to subject and object inference data is obvious.

The transformation. In each of three different conditions, Rodrigues presented experimental subjects with four items that fit the following format: "You dislike [or like] *o*; how does *o* feel about *x* [an issue the experimental subject either favored or opposed]?" In each condition 20 subjects responded to each item by indicating whether he or she predicted that *o* had a positive feeling or a negative feeling toward the issue. When both the person, *o* (i.e., the sentence subject), and the issue, *x* (i.e., the sentence object), were negatively evaluated, 13 of Rodrigues's 20 experimental subjects inferred a positive verb and 7 inferred a negative verb; Gollob expressed the triads as S–V–O sentences and in this case assigned a "probability score" of 13 to the $- + -$ sentence and a score of 7 to the $- - -$ sentence. The other three items were dealt with in a similar manner, so that an S–V–O item set consisting of eight sentences was generated. The S–V–O model was then used to analyze the resulting $2 \times 2 \times 2$ item set.

When S–V–O item sets are generated in this manner, the relevant-bias hypothesis is forced to hold perfectly and therefore cannot be tested in data of the type collected by Rodrigues. Gollob (1974b, pp. 305–306, 313) emphasized this point and discussed ways of taking this fact into account in interpreting results of S–V–O analyses that are conducted on data of this type. It should be emphasized, however, that the transformation is rarely needed because S–V–O research typically involves collection of the type of $2 \times 2 \times 2$ data sets for which it was designed.

Anderson's recommendation. Rather than apply the transformation used by Gollob, Anderson (1977, pp. 151–153) recommends that 2×2 analyses of variance be applied to data of the type collected by Rodrigues. Let us use Rodrigues's data to discuss the interpretation of such an analysis. Averaging over Rodrigues's three conditions, the mean probability scores for the sentences containing a positive verb were $+ + +$ (18.7), $+ + -$ (4.0), $- + +$ (7.7), and $- + -$ (13.0). For convenience of exposition we subtract the "midpoint" of 10 from each of these scores before doing the analysis of variance; if the grand mean is larger than zero on this new scale, we conclude that

over half of the experimental subjects inferred the positive verb. In the two-way analysis recommended by Anderson, the weights given to the standard analysis of variance contrasts that define the grand mean, S, O, and SO effects are .85, .50, 2.35, and 5.00, respectively.[4] The large weight given to the SO interaction suggests that on the average, people we like are judged more likely to agree with us on issues than are people whom we dislike. Thus, in the 2×2 design Rodrigues used, the predicted effects of Heiderian balance are shown by the presence of a large SO interaction. In an S–V–O analysis, on the other hand, Heiderian balance leads to a prediction of an SVO interaction. The following discussion shows that this difference is no cause for alarm.

Comparison of the two analyses. The most important thing to realize in comparing the two analyses of verb inferences is that there is an exact correspondence between the grand mean, S, O, and SO sources, respectively, in the two-way analysis recommended by Anderson, and the V, SV, VO, and SVO sources in the three-way analysis used by Gollob. Standard analysis of variance procedures give identical weights to the contrasts that define appropriately paired sources of variation in the two designs. The weights given to the grand mean, S, O, and SO in the three-way design are all necessarily equal to zero. *Thus, except for the names given to the sources of variation, the two methods of analysis yield identical results.* Since the two analyses have identical psychological implications, the choice between them should be made on the basis of which labels are most convenient to use.

When Gollob's three-way analysis is used, one obtains results directly interpretable in terms of the hypothesized cognitive biases. When Anderson's two-way analysis is used, however, much unnecessary confusion results. Consider, for example, a situation in which Heiderian balance is predicted to have an important effect on subject, verb, and object inference judgments. When using three-way analyses, an SVO interaction is implied by the Heiderian balance prediction regardless of the type of inference. When using two-way analyses, however, the same hypothesized balance tendency leads one to predict a VO interaction in the case of subject inferences, an SO interaction in the case of verb inferences, and an SV interaction in the case of object inferences. The confusion is further compounded by the fact that in standard S–V–O item sets, SO, SV, and VO refer to three different hypothesized cognitive biases—none of which are equivalent to traditional Heiderian balance. The method Gollob used to transform two-way analyses into equivalent three-way analyses avoids these difficulties and enables the S–V–O model's concepts and notation to be used in a consistent manner in investigating data involving different types of judgments and different types of data collection procedures.[5]

In summary, in order to use the S–V–O model to reanalyze their data, Gollob transformed Rodrigues's (1968) and Osgood and Tannenbaum's (1955) 2×2 data sets into equivalent $2 \times 2 \times 2$ data sets. Contrary to Anderson's (1977, p. 152) assertion, there is nothing artificial or misleading about the transformation. It avoids the notational confusion that Anderson's method introduces, and provides a convenient way to conceptualize the results in a 2×2 data set in terms of the hypothesized cognitive biases used in the S–V–O system.

A Multiplicative Model for Verb Inference Data

With the purpose of illustrating an alternative to the S–V–O approach, Anderson recommends using Oden and Anderson's (1974) multiplicative model to study verb inference judgments that are obtained in response to sets of sentences constructed by using one verb in combination with several quantified levels of sentence subject and object. The data Anderson uses to illustrate the model consist of judges' responses to stimuli of the

[4] When an analysis is done on the probability scores for the sentences containing negative verbs, the grand mean and weights have the same absolute value but are reversed in sign.

[5] Although Anderson used a rating scale example to present his criticism of the procedure Gollob used to apply the S–V–O model to two-day designs, the issues involved are identical to those discussed above.

following type: "Mr. X is *very sociable*; how likely is it that he will *socialize with moderately unsociable* people?" In both the sentence subject and object positions, the adjective was graded in five levels from very unsociable to very sociable and the verb *socialize with* was used in all sentences. Although the method Anderson (1977) and Oden and Anderson (1974) used to test the goodness of fit of their multiplicative model is not entirely appropriate,[6] it is clear that if a constant term is added to their model, it can provide a reasonable account of the data in Anderson's Figure 3 (1977, p. 151).

Anderson recommends use of a nonconfigural model. Without attempting to explain the apparent paradox, Anderson presents the *nonconfigural* multiplicative model as providing a method of attacking problems due to configurality (1977, pp. 147–148, 156). Anderson seems to be saying we should study problems due to subjects' configural responding by avoiding them. For example, to study verb inferences using the approach Anderson recommends, the data sets investigated must meet several restrictions explicitly designed to eliminate configural responding on the part of the judges: (a) The data set must contain only one verb, (b) the semantic relationship between the sentence subject and verb, and also the semantic relationship between the verb and object, must somehow be qualitatively fixed in all sentences in the data set, (c) the sentence subject and verb must be capable of being quantitatively varied without disturbing the fixed qualitative semantic relationships, and, finally, (d) the likelihood judgment must be a multiplicative function of the scale values assigned to the sentence subjects and objects. Oden and Anderson's results are of interest in their own right because they show that data sets in which these stringent requirements are met can in fact be constructed. Since, however, none of the conditions required by Oden and Anderson's method need to be met when using the S–V–O approach, it is not clear what relevance their results have for assessing the usefulness of the S–V–O formulation.

Anderson's approach and the S–V–O approach are concerned with different problems for which different models and different data collection procedures are appropriate. If one's interest is in identifying sets of social judgment data that are highly quantified and can be fit by nonconfigural models, the approach recommended by Anderson is preferable to the S–V–O approach. On the other hand, the S–V–O approach is preferable if one's interest is in studying social judgments in the context of $2 \times 2 \times 2$ item sets in which configural responding can be investigated in terms of the hypothesized cognitive biases.[7]

Use of Simple Algebraic Models in the Analysis of Social Judgment

In the last few pages of his critique, Anderson (1977, pp. 153–156) argues that problems in implicit personality theory and general social inference can best be investigated by use of the methods of data analysis and data collection that he typically uses in his own work (cf. Anderson, 1970, 1971). Although

[6] Except for a change of notation, the multiplicative model presented by Anderson (1977) and Oden and Anderson (1974) is

$$y_{ij} = A_i B_j,$$

where y_{ij} denotes the judged likelihood for the sentence containing the ith sentence subject and the jth object, and A_i and B_j denote the scale values associated with the stimuli. Anderson (1977, p. 151) notes that the data in his Figure 3 form a diverging fan of straight lines, which is characteristic of the multiplying model, and on this basis he concludes that the data support the model given above. Oden and Anderson (1974) report that an analysis of variance test of goodness of fit indicated that the data did not deviate significantly from the linear fan pattern. However, unless a transformation of the response scale is allowed (an option not mentioned by Anderson or by Oden and Anderson), these methods test the goodness of fit of the model

$$y_{ij} = A_i B_j + \text{constant},$$

rather than the model proposed by Oden and Anderson. Thus, in the absence of some independent a priori certainty that the constant term in the model is zero, the test of goodness of fit used by Anderson (1977) and by Oden and Anderson (1974) is inappropriate.

[7] Although some work relevant to quantifying various notions of cognitive bias has been reported (e.g., Gollob, 1968b; Gollob & Fischer, 1973; Gollob, Rossman, & Abelson, 1973, p. 29; Heise, 1969), at present the S–V–O model assesses the biases only at the level of "present" or "absent."

these methods are based on simple algebraic models that are essentially nonconfigural in nature, it is clear that many important problems in social judgment can be effectively approached by their use. Gollob has used such methods when they have been appropriate for the problems under investigation.

One such example is provided by Gollob's (1965, 1968b) study of impression formation and word combination in simple subject–verb–object sentences. In that study, judges made evaluative ratings of men described by sentences that were constructed from factorial combination of several adjectives, verbs, and objects (e.g., "The vicious man likes beggars," "The kind man praises communists"). As part of the larger study, Gollob used several different models to analyze the mean evaluative ratings (averaged over observations and adjectives) of verb–object combinations. One set of analyses compared two multiplicative models of verb–object integration. One model treated the direct evaluative ratings of the isolated verbs and objects as interval-level scale values, and the other treated the verb and object main effects as interval-level scale values in the model. (The latter model is the type of algebraic model whose use is advocated by Anderson.) Interestingly, although the model based on the main effects estimated 2.5 times as many free parameters as did the model based on direct evaluative ratings of isolated sentence components, it was slightly *less* effective in accounting for variation in the ratings of the verb–object combinations.

Gollob (1965, 1968b) also tested models more complex than the ones just described. Using Gollob's (1968a, 1968c; Tucker, 1968) Factor Analysis of Variance (FANOVA) model, it was found that two multiplicative terms were needed in order to adequately account for the variation in ratings of the verb–object combinations. Each of the multiplicative terms suggested a different aspect of meaning that contributed to the evaluative ratings. The types of model whose use is advocated by Anderson are nonconfigural and do not allow for the possibility that more than one multiplicative term can affect judgments. Wyer and Hinkle (1976) also have reported social judgment data in which the FANOVA heuristic of representing the data by a series of multiplicative components was found to be useful. And finally, Gollob and Rossman (1973) found that both evaluative and potency judgments of sentence components were important in accounting for potency judgments of sentence subjects. These few examples emphasize that although simple algebraic models such as those advocated by Anderson often are useful, they are far from complete in their ability to describe social judgment data. One must be prepared to modify one's models and one's methods of analysis as dictated by the characteristics of the problems of interest and the data at hand.

Anderson's critique implies that if a model has a simple algebraic form and passes appropriate tests of goodness of fit, then that model and its associated scale values are correct, valid, and subjectively real. Anderson seems to forget that radically different models can be roughly equivalent in their ability to fit data and that the choice between such models must be made on the basis of convenience, theoretical considerations, or other substantive grounds. Anderson might agree, however, that it is important to temper one's enthusiasm at finding a model that fits data well by considering Tukey's (1977, p. 586) admonition concerning model fitting: "Even when we see a very good fit—something we know has to be a very useful summary of the data—we dare not assume that what is fitted is of exactly the right form; we dare not believe we have found a natural law."

In summary, Anderson's critique ends by advising researchers in implicit personality theory to focus their work sharply on the investigation of problems that are amenable to quantitative analysis by use of simple algebraic models. In contrast to Anderson's recommendation that we tailor our questions to fit a particular research paradigm and method of analysis, the present article recommends that we tailor our research paradigms and data analysis methods to fit our questions.

Postscript: Anderson's Reply Is Not Responsive to the Issues

This postscript is a rejoinder to the immediately following article by Anderson (1979). The preceding part of the present article directly responds to every major criticism Anderson (1977) presented in his original critique of the S–V–O formulation. Anderson's (1979) article on the other hand, does not attempt to rebut the points made above; it merely repeats a few of the many questionable claims Anderson made in his original paper. This postscript considers (a) Anderson's shift of emphasis away from technical issues, (b) Anderson's insistence that weights obtained from S–V–O analyses be applied to single sentences, whereas Gollob has specifically said that they apply to item sets, and (c) Anderson's claims concerning goodness of fit.

Indeterminate Criticism

Apparently the central thrust of Anderson's criticism of the S–V–O formulation has shifted. In his reply, Anderson (1979) complains that the main point of his original paper is becoming lost in a mass of technical detail. This is a surprising complaint. Anderson's (1977) original paper spent a dozen pages presenting technical criticisms, but only three pages on what he now describes as "the main issue." Thus, contrary to the implication of his reply, Anderson's critique was primarily technical in nature. In the first part of the present article I have shown that

Anderson's (1977) technical criticisms of the S–V–O approach are refutable, and that the methods Anderson proposes for dealing with problems of configurality are ineffectual. Rather than discuss my refutations of his criticisms concerning technical issues, Anderson now states that technical issues played a minor part in his original critique.

Choice of Problem

Anderson begins his reply by saying that the "main point" of his original critique and of his reply is that an S–V–O analysis "yields a theoetical representation of the response to a *single sentence* that is arbitrary and indeterminate" (p. 950, emphasis added). Thus, Anderson has ignored the explicit statement that "the weights obtained in an S–V–O analysis are interpreted as reflecting the direction and importance of biases in accounting for variation *within individual item sets*—not within individual sentences" (p. 940 above). Moreover, at the end of his reply, Anderson (1979) implies that Gollob (1974b, Equation 1, p. 292) presented the basic S–V–O model as applying to single sentences, regardless of context. Contrary to Anderson's implication, Gollob (1974b, p. 292) specifically stated that the model equation and weights apply to sentences in the context of item sets. Since the weights obtained in S–V–O analyses do not apply to single isolated sentences, Anderson's "main point" is irrelevant in evaluating the usefulness of S–V–O analyses.

Anderson (1979) complains that Gollob has not emphasized that the weights obtained in S–V–O analyses must be interpreted in the context of the particular item sets being analyzed. This is an odd complaint. The derivation of the relevant-bias hypothesis, discussions of how weights should be interpreted, and the use actually made of weights in empirical work all show that S–V–O weights must be interpreted in the context of the item sets being analyzed. Moreover, with the single exception of Anderson (1977), every study conducted within the S–V–O framework has considered theoretical bases for making a priori predictions of the specific ways in which the weights given to biases will vary as a function of the particular content of the item sets being investigated. Finally, the results of most S–V–O studies demonstrate how the approach is used to compare the contributions of hypothesized cognitive biases across item sets of varying content in a systematic and psychologically meaningful way.

Anderson (1979) defines "operative weights" as "the weights that were operative in the actual judgment of each sentence" (p. 950). Because S–V–O analyses do not yield estimates of the operative weights, Anderson concludes that the S–V–O model is indeterminate, meaningless, untestable, and unable to deal with configural responses. It seems that Anderson's concern with operative weights prevents him from seeing any value whatsoever in studying and making predictions about other kinds of weights. He ignores the fact that the whole purpose of the S–V–O model is to conceptualize social cognition problems in the context of item sets of eight sentences; the S–V–O model was not designed to provide estimates of operative weights.

Although the problem of estimating operative weights is not the problem addressed by S–V–O analyses of $2 \times 2 \times 2$ item sets, estimation of such weights has been the focus of other research conducted by Gollob and his colleagues. For example, studies of impression formation by Gollob (1968b), Gollob and Fischer (1973), and Gollob and Rossman (1973) have estimated the values of operative weights that are given to various cognitive biases. In these studies, quantified indices of some of the S–V–O biases are used in place of the qualitative indices considered in the $2 \times 2 \times 2$ analyses. The basic ideas underlying the S–V–O biases have been useful in both types of studies.

In summary, Anderson (1977, 1979) does not attempt to evaluate what the S–V–O approach does, how it has been used, or even what claims have been made for it. His criticisms might be germane to other models constructed for other purposes; they surely are not relevant to the S–V–O model.

Goodness of Fit

Anderson (1979) emphasizes that he and Gollob are in agreement on several important methods that should be used in testing goodness of fit. Agreement about what methods *should be* used, however, is not relevant to the present debate. Anderson's original critique did not say Gollob's beliefs were in error; it said that the methods Gollob actually used to test goodness of fit were in error. The nonpostscript portion of the present article presents several specific examples that show Anderson's criticism is incorrect and misleading.[8]

[8] Since Anderson is well known for the stern admonitions he dispenses to those who fail to test goodness of fit, it is interesting to consider the fol-

Anderson (1977, 1979) sets up a classic "straw man" about goodness of fit by emphasizing that if all seven biases in the S–V–O model are assumed to be meaningful in every item set, the model cannot be invalidated. Although this statement is correct, it ignores the fact that only *restricted versions* of the model are discussed in S–V–O work. I am not aware of even one S–V–O study that has assumed that all seven biases will be relevant in every item set studied. It is obvious, and has been repeatedly stated, that the cognitive biases of the model must be psychologically meaningful on a priori grounds in order to be taken seriously. As far as I know, Anderson is the only person who talks as though anyone would expect all seven biases to be psychologically meaningful in every item set.

Contrary to Anderson's (1977, 1979) accusations, the present article has demonstrated that Gollob, Wyer, and their colleagues have consistently used appropriate methods to test the goodness of fit of several restricted versions of the S–V–O model. Anderson's (1979) sole response to this demonstration is to assert that restricted versions of the model are "merely plausible hunches" and have "no special theoretical status." Such polemic cannot take the place of careful model analysis and evaluation.

Conclusion

In summary, Anderson's (1979) reply presents as extreme a distortion of the S–V–O approach as did his original critique. I urge readers who are interested in more than the heat involved in this exchange to read Anderson's original critique, together with some examples of research conducted within the S–V–O framework. The research examples are important in showing how the S–V–O framework has been used and in demonstrating its usefulness in dealing with substantive issues in social cognition.

---

lowing points. In discussing goodness of fit, Anderson (1979) refers to Table 2 of his original article and says that the restricted S–V–O model implied by the relevant-bias hypothesis "failed badly in the representation of Design A." It is ironic that neither his original paper nor his reply tells the reader whether the restricted model showed statistically significant lack of fit. Nor does he mention that the restricted model accounted for 92% of the item set variation, or that the nonrelevant biases all had smaller weights than did any of the relevant biases.

Indeterminate Theory: Reply to Gollob

Norman H. Anderson
University of California, San Diego

The central criticism of the balance triad model presented by Anderson concerned its theoretical indeterminacy: The same sentence can receive quite different theoretical representations, depending on arbitrary choice of other sentences. In other words, the balance triad model gives an indeterminate description of the cognitive processes involved in the judgment of any given sentence. Gollob's reply agrees on this point.

The Main Issue

The central criticism in my discussion of the balance triad model is conceded by Gollob to be correct (Anderson, 1977; Gollob, 1979). Since this central issue is becoming lost under a mass of technical detail, it deserves reemphasis in simple terms: The balance triad model yields a theoretical representation of the response to a single sentence that is arbitrary and indeterminate.

At face value, the balance triad model is simple. Seven balance tendencies or "cognitive biases" are hypothesized. They determine the judgment of each single sentence by a weighted sum model. The model conceptualizes "how the information carried by the various cognitive biases is combined by perceivers in making social inference judgments." Specifically, it assumes that the seven cognitive biases "are combined linearly to yield the judged probability of a sentence type" (Gollob, 1974, p. 292). Of primary concern, therefore, is the importance or operative weight of each cognitive bias.

Unfortunately, the model analysis yields indeterminate estimates of these weights. To estimate the weights requires the use of seven additional sentences to form a 2^3 item set. In principle, that is legitimate and proper. In this particular case, it has an illegitimate consequence: The estimated weights for the given sentence can have quite different values, depending on arbitrary choice of the additional sentences. Each sentence thus has many different theoretical representations; each representation tells a different theoretical story. Since the choice among them is arbitrary, the theoretical representation of the cognitive biases is indeterminate.

This indeterminacy was the central criticism of my article. This was the point of the "thought experiment." This point was verified in the actual experiment. The same sentence did indeed have two quite different theoretical representations. Each representation created a quite different theoretical picture of the underlying cognitive processes.

In his reply, Gollob (1979) agrees with this criticism: The model "assumes that the judgment of a given sentence is a linear combination of the various psychological biases," but the model analysis "does not yield direct estimates of the weights for that linear combination" (p. 940).

We are thus faced with a peculiar theoretical situation in which there are two different sets of weights. One set refers to the basic cognitive model and may be called *operative weights*; these are the weights that were operative in the actual judgment of each sentence. The other set may be called *estimated weights*; these are the weights that are obtained when the same basic model is

actually applied to these same judgments. But these estimated weights are not the operative weights. This is a strange kind of model analysis. What can it mean?

Gollob argues that the model analysis actually measures relative importance of the cognitive biases, not for any one sentence but for an item set of eight sentences. But this argument begs the question, for it rests on mere assumption that the model is correct. If the model is not correct for any single sentence, averaging over a set of sentences does not necessarily improve it.

The basic problem, as I have pointed out in other discussions of balance theory, is the problem of configurality. In my experiment (Anderson, 1977), for example, *harms* and *hinders* were interpreted in terms of configural relations to the other parts of the sentence. Such configurality is an important problem, but one to which the balance triad model is insensitive. No doubt Gollob is correct in saying that configurality poses no special problem to the balance triad model. That is not because the model solves the problem, however, but because it buries it by averaging over the varied configuralities involved in eight different sentences.

As it stands, therefore, the balance triad model should perhaps not be called a model at all. Instead, it illustrates the Procrustean, curve-fitting properties of analysis of variance.

In my original article (Anderson, 1977), I concluded that

> The balance triad model of Gollob (1974b), Insko et al. (1974), and Wyer (1975b) represents a notable attempt to bring needed precision into balance theory. If successful, this model could fractionate and measure each of several coacting balance tendencies. In Gollob's applications especially, this attempt went beyond the affective relations of traditional balance theory to consider semantic relations and a more informational analysis.
>
> Despite the present criticisms, the work of Gollob, Insko, and Wyer is important in representing thoughtful and serious attempts to break through the limitations of traditional balance theory to a new approach. There is no doubt about the interest and potential value of this approach. There is, of course, the question of its validity. (p. 154)

The question of validity still remains, more serious than before.

Goodness of Fit

Since the central criticism of the balance triad model was correct, technical details no longer seem to have much relevance. Although there is much to question in Gollob's comments on technical details, they require only minor qualifications of my original discussion. Accordingly, I wish to comment only on Gollob's implication that I have not correctly represented his position on goodness of fit.

On goodness of fit, I explicitly noted that "as Gollob (1974b) has carefully pointed out, the balance triad model can always fit the data perfectly" and that Wyer and especially Gollob "have given serious attention to this problem" of obtaining a test of goodness of fit (Anderson, 1977, p. 145). I also explicitly noted that "restricted versions of the complete balance triad model can readily be tested" (p. 146), again in agreement with Gollob's position. And in general, I completely agree with Gollob that common sense is a much-needed ingredient in model analysis (e.g., Anderson, 1976, in press).

Of course, the basic problem in testing the balance triad model still remains. The restricted versions of the model that can be tested have no special theoretical status. They are merely plausible hunches. If the test rejects the null hypothesis that some weight is zero, that only means that the hunch was wrong and that the weight is not zero after all.

Just this situation arose in the comparison of Designs A and C in Table 2 of my article. The two designs yielded two quite different theoretical representations of their four common sentences. The relevant-bias hypothesis succeeded in the representation of Design C but failed badly in the representation of Design A. I did not take the latter failure as a criticism of the theory, however, because the general model places no restriction on the weights. Gollob evidently concurs; referring to these two theoretical representations in his reply, he states that "both can be correct." In other words, failure of the relevant-bias hypothesis is not considered as a failure of the general model.

Indeed, Gollob (1974) explicitly asserts that "when no restrictions are placed in the weights . . . the model is useful as a method

of decomposing the data from an item set into psychologically interesting components" (p. 293). But when no restrictions are placed on the weights, the model is admittedly untestable. To say that it yields a meaningful decomposition is to assume its truth regardless of testability. In short, the general model disallows only its own disproof.

One further comment on goodness of fit should be added in light of Gollob's reply. It now is clear that the estimated weights obtained from the model analysis are not the weights in the operative model. Such model analyses would seem to have no relevance whatever to testing the operative model.

A Question of Understanding

In his reply, Gollob states that he never intended to make and never did make the theoretical interpretation to which my central criticism was directed. His present position, certainly, is quite different. I apologize for any deficiencies in my understanding, but I did spend considerable time on the article trying to be correct and fair. Since Gollob finds fault with my understanding, I feel it appropriate to add three remarks in self-defense.

First, I sent the original and the revised preprint of my article to Gollob and to other interested parties, together with covering letters asking for comments and criticism. Not one of the replies that I received suggested that my central criticism rested on a misunderstanding of the balance triad model.

Second, it was an editorial requirement that I verify the thought experiment with an actual experiment. But the sole purpose of the thought experiment was to illustrate the theoretical indeterminacy. Neither it nor the actual experiment had any other point or purpose. If Gollob's present position had been clear then, both the thought experiment and the actual experiment would have been unnecessary. Since this point was not raised in the editorial process, it seems proper to say that I was not alone in my understanding of Gollob's position.

Finally, my understanding of Gollob's (1974) theoretical position still seems to me to agree with his statements in that article. It is true, to be sure, that the numerical calculations to estimate the weights require use of a 2^3 item set of sentences. The issue is not how the weights are calculated, however, but what they mean. Gollob (1974) repeatedly refers to the weights of the cognitive biases in inferences or judgments to single sentences; these are the operative weights. No warning is given about any other set of weights. No warning is given that the estimated weights obtained from the model analysis are not the operative weights for any sentence.

Quite the contrary. The basic model (Gollob, 1974, Equation 1, p. 292) explicitly represents the judgment of the given single sentence as a weighted sum of cognitive biases; the same paragraph asserts a few lines later that the model analysis provides "least squares estimates of the weights." If Gollob (1974) considered that two different sets of weights were involved, he should have said so then. Since Gollob (1974) does not even allude to two different sets of weights, the complaints in Gollob (1979) seem ill-taken.

Negative Emotional Biasing of Unexplained Arousal

Christina Maslach
University of California, Berkeley

Schachter and Singer's two-factor model of emotion argued that a state of unexplained arousal could as easily be labeled "euphoria" as "anger," depending on the cognitions available in the immediate situation. A theoretical critique of this model suggests that the individual's search for a cognitive explanation of an arousal state is (a) more extensive than originally hypothesized and (b) biased towards negative emotional labels. Because of methodological weaknesses in the original study, a new paradigm, utilizing amnesia for hypnotically induced arousal, was developed to test the contrasting hypotheses. Subjects either did or did not experience unexplained arousal in the presence of a confederate who was displaying either happy or angry emotions. The results of this modified replication, as well as of an exact replication by Marshall and Zimbardo, fail to support the Schachter and Singer model and demonstrate the negative bias in the process of identifying unexplained internal states.

The study of emotion has been slowed by a lack of consensus about the scientific conceptualization of this phenomenon that we each know so well at a personal level. While some researchers define emotion in terms of motives or behavioral responses, others focus on the sensations of bodily changes, subjective experience, or cognitive processes. Within the more cognitive models of emotion, the most influential work has been the classic experiment by Schachter and Singer (1962). Two dimensions of emotion were independently manipulated in the study: physiological arousal and cognitive cues. Some physiologically aroused subjects were correctly informed as to the source of their arousal, while others were either uninformed or given an erroneous explanation. Crosscutting this manipulation of arousal was the manipulation of the emotional cues presented in the immediate situation. Subjects interacted with a confederate who was acting either euphoric or angry. The results appear to show that aroused subjects without a prior appropriate explanation used the available situational cues to label their state in emotional terms. If they were with a euphoric person, they labeled their own arousal as "euphoria," but if they were with an angry person, the same physiological arousal was labeled as "anger." Unaroused subjects or those with an appropriate explanation for their arousal were reported to be uninfluenced by the emotional cues provided by the confederate.

This experiment represented an important conceptual change from previous theoretical positions, all of which postulated a direct causal relationship between physiological arousal and cognitions about emotional states. In contrast, Schachter and Singer proposed that the factors of physiological arousal and emotional cognition could function independently and that they interacted with each other to produce a true emotion. In addition to this interactionist model, Schachter and Singer made a second signifi-

cant contribution by demonstrating the importance of situational determinants of emotion. The theoretical impact of this study cannot be overestimated, foreshadowing as it did the rise of cognitive analysis in social psychology. This general line of thinking played an important role in the current development of attribution theory, as a result of its emphasis on the role of cognition in defining reality. Furthermore, it has inspired several new lines of theory and research about a variety of internal feeling states, including fear, hunger, passion, and pain (see London & Nisbett, 1974; Mandler, 1975; Schachter, 1971; Walster, 1971).

However, despite its ingenious paradigm and its theoretical contributions, the Schachter and Singer (1962) study cannot be accepted uncritically. Although the conclusion is provocative, a careful inspection of the findings suggests that it is not, in fact, supported by the evidence. The initial data analysis reveals no significant difference in self-reported emotion between any of the unexplained arousal groups and the placebo control groups. Although the authors point to the predicted pattern of means within each emotion condition, the absolute size of the effects is minimal, since the difference in emotion between any of the groups amounts to less than one single scale unit on a 9-point scale. The theory also requires absolute qualitative differences in emotion as well as relative differences in emotion ratings between the experimental groups of the euphoria and anger conditions. However, the means of all conditions reflect a feeling of "slight happiness," regardless of the emotional cues provided by the euphoric and angry confederates.

The behavioral data are also weak. The comparison between unexplained arousal groups and placebo controls reaches statistical significance only in the anger condition, not in the euphoria one. Even though this pattern of "anger units" is in line with the authors' theory, the size of this response certainly is not. The low mean score for subjects with unexplained arousal could represent merely one instance of verbal agreement with the angry confederate's position over nearly 20 minutes of interaction. Somewhat stronger behavioral differences emerged only after a sizeable number of subjects were discarded in an internal analysis.

One possible reason for the lack of empirical support may be that there are methodological flaws in the design of the study (see Maslach, 1979, for a review of these problems; see also the critiques by Lazarus, 1968; Leventhal, 1974; and Plutchik & Ax, 1967). Given the theoretical significance of the Schachter and Singer study, one would expect that more methodologically rigorous replications would have already been done. Surprisingly, only one attempt has been made. Marshall and Zimbardo (1979) tested 80 male subjects in a partial replication of the Schachter and Singer paradigm for the euphoria condition. However, they found no empirical support for Schachter and Singer's conclusions. Subjects who had received the standard epinephrine injection, along with an "inadequate" explanation of its side effects, did not differ from placebo controls in either emotional affect or behavior. Furthermore, when the arousal was made stronger and more salient, subjects reported a *negative* emotional state, rather than the positive "euphoria" predicted by Schachter and Singer.

Alternative Views

The lack of empirical support for the conclusions advanced by Schachter and Singer (1962) forces us to consider alternative hypotheses. One possibility is that the Schachter and Singer theory is incorrect. The qualitative differentiation of emotions may have some basis other than situational cues. Moreover, an undifferentiated autonomic arousal may not be the physiological basis for emotion. The Schachter and Singer model may also be incorrect in its assumption that autonomic arousal is a neutral activator steered by available cognitions. Marshall and Zimbardo's findings suggest that attending to such arousal may have a negative quality that will overshadow positive emotional cognitions. If so, this would argue for the importance of physiological feedback in determining the quality (and not just the quantity) of the emotion.

An alternative interpretation is that the Schachter and Singer theory is correct but that the particular paradigm did not provide an adequate test of it. Schachter and Singer present their model as an explanation of emotion in everyday situations, in which the physiological and cognitive factors are completely entwined. However, they test their model by separating the two factors and creating a situation of unexplained autonomic arousal. Such a situation is rather rare and unusual in everyday life, and it may be erroneous to generalize from this special case to more common emotional experiences. Because of its novelty, the experience of unexplained arousal may not be affectively neutral, but may instead produce a bias in the search for an emotional cognition.

Negative biasing. The idea that unexplained arousal is an affectively neutral state seems intuitively correct only for someone who is experiencing such arousal for the first time (such as a child), and who must look to other people and/or the situation to make sense of this strange and puzzling experience. The concept does not apply as well to people who have had numerous experiences pairing arousal with emotional labels and with appropriate arousal instigators. If they were to feel aroused without knowing why, it would not only be an unusual experience but a disturbing or even frightening one, since this uncertainty would be felt as a loss of personal control over their own internal states. Indeed, the concept of unexplained arousal is very close to the clinical definition of "free-floating anxiety," which is always characterized by negative emotional affect. Therefore, unexplained arousal may generate a *biased,* rather than an unbiased, scanning of evidence and alternative hypotheses. That is, the search for an appropriate cognitive label for the arousal could be biased toward available negative instances. A negative bias also seems more probable because noticeable physical arousal is a far more common concomitant of negative emotional experiences than of positive ones (with the possible exception of sexual excitement).

An expanded search. This alternative view still accepts the Schachter and Singer notion of a cognitive search for an emotional explanation. However, their experimental test of the search process was a narrow one that did not consider the full range of information that a person might have used. They only assessed the impact of the confederate's mood on the subject and ignored other information in the immediate situation or in the subject's life experiences. For example, they did not consider the possibility that a person will search his or her memory for past events or prior comparable situations that would provide an appropriate explanation for the current state of arousal. Subjects might have tried to recall similar situations in which they had felt aroused (such as being in a testing situation or visiting a doctor). They might have then used these memories to derive an appropriate emotional cognition ("I must be getting upset about the tests they are going to do, since I always worry about failing" or "I've never liked getting stuck with needles by doctors, so that's why this injection bothers me"). To the extent that subjects' explanations were based on their past history, on attributions about their health, or on nonsocial aspects of the environment, it might explain the relatively weak impact of the confederate's mood or the substantial within-condition variance that attenuated treatment effects.

Although Schachter and Singer (1962) postulate that the relevant emotional cognitions arise from the immediate *situation,* they operationalize this concept in terms of a *person* who serves as a social comparison referent for the subjects. They predict that it is the emotion displayed by this comparison person that will be the "appropriate cognition" which the subjects use to label their own arousal. However, such a prediction must rest on the assumptions that subjects will view the other person as (a) being someone similar and comparable to them, (b) responding to a set of situational demands that are also impinging on the subjects, and (c) behaving in an appropriate way to these demands.

The first assumption may be justified in the experiment, since the comparison person was of the same sex and age as the subject and had a similar educational background. There is less evidence to support the other

two assumptions. An examination of the experimental procedure reveals that the comparison person was not always responding to the same situation that confronted the subject. For example, there is nothing inherent in the messy experimental room that should cause people to experience euphoria. Given this lack of situational inducements,[1] the confederate's playful behavior says more about his particular personality than it does about the appropriate way to respond to a situation. This *dispositional* interpretation is made especially salient by the confederate's own statement that "this is one of my good days" (Schachter & Singer, 1962, p. 384). From the subject's point of view, whatever is causing the confederate to feel euphoric is something unique to him and not something that they share in common. In contrast, the anger condition does provide some relevant situational demands, since the confederate's anger is directed at a long and insulting questionnaire that the subject is also completing.

Finally, there is insufficient evidence that subjects would view the confederate's behavior as appropriate to the situation. In both experimental conditions, the confederate behaved in unusual ways (agitated, manic, and assertive), especially compared to the norm of quiet compliance that is generally characteristic of research subjects. Spontaneously playing with paper airplanes and hula hoops is not a typical thing to do in a scientific laboratory, nor is abruptly walking out of the experiment. To the extent that subjects perceive the confederate as acting in idiosyncratic, unusual, or inappropriate ways, he loses his social comparison reference power, and subjects would not be likely to label their own arousal in terms of their cognitive interpretation of his mood.

Current Study

The current research was designed to further investigate the process of a cognitive search for the causal antecedents of unexplained arousal. It involved a modified replication in which procedural elements were altered to correct some of the original methodological problems. These improvements included the use of a hypnotic induction to produce an arousal state, rather than a drug injection. Previous research has demonstrated that marked physiological changes can be produced hypnotically (see the review by Sarbin & Slagle, 1972). In addition, the use of hypnosis allowed for a better degree of experimental control over the onset and the maintenance of the physiological arousal. The lack of an explanation was produced by a posthypnotic suggestion for amnesia of the true cause of the arousal. Subjects experienced physiological arousal but did not know why the arousal was occurring and did not remember that it was due to the hypnotic suggestion. Posthypnotic amnesia is a phenomenon that has been demonstrated in numerous studies (see Cooper's review, 1972) and is believed to involve a temporary disruption of the normal retrieval process (Evans & Kihlstrom, 1973). Cues that normally aid the process of recall are not utilized as they would be in normal waking memory.

Second, the behaviors of the two emotion conditions were made directly comparable—the nature, level, and timing of the activity were equivalent in both conditions, and only the confederate's obvious emotional state (happy or angry) was varied. The reasons given for the confederate's emotion were ones that the subject could readily share, and the confederate's behavior appeared believable and appropriate in the laboratory setting. Finally, several measures were added to the study, both to assess the validity of

---

[1] In a personal communication (1976), Bibb Latané (who was the confederate in the euphoria condition) pointed out that the confederate exerted a great deal of pressure on the subject to join him in the "euphoric" behavior and that this constituted a relevant situational inducement. However, this raises even more problems in interpreting the data, since the subject's behavior would then reflect social conformity rather than an experienced emotion. One could also argue that once subjects had been induced to imitate the confederate, they would make judgments of their emotional state on the basis of observing their own behavior (Bem, 1972; Walters & Amoroso, 1967). According to this self-perception interpretation, the "appropriate cognition" is not the mood of the confederate but the behavior of oneself (which has been induced by the confederate).

the experimental manipulations and to reflect more precisely any differences in emotional behavior.

Hypotheses. The proposed modification and extension of the concept of cognitive search leads to some different predictions from those made by Schachter and Singer (1962). These competing hypotheses center on the questions of (a) whether the search is limited to, or goes beyond, the immediate situation and (b) whether the search is unbiased or biased. On the first question, Schachter and Singer imply that subjects will rely primarily on the information provided by the confederate to label their own unexplained arousal. In contrast, the current study predicts that subjects will also utilize information from both their past and present life. Thus, their emotional response will be more independent of the confederate's mood and less constrained by the immediate situation. On the second question, Schachter and Singer argue that subjects with inadequately explained arousal will engage in an unbiased search for a cognitive label. In contrast, the current study proposes that regardless of the confederate's display of affect, the cognitive search will be biased towards labels for negative emotions, since a state of unexplained arousal is initially anxiety provoking for adult subjects. For those not experiencing arousal or those given an appropriate explanation for their arousal, both theories agree on the absence of a search for cognitive labels of emotion—and thus an absence of an experience of emotion.

Method

bjects

Forty-eight undergraduate subjects (25 males and females) [2] were drawn from the introductory ychology course subject pool at Stanford Univer- y and paid for their participation in this experi- nt. All of the subjects had received scores of high pnotic susceptibility on the Harvard Group Scale Hypnotic Susceptibility (Shor & Orne, 1962).[3] irty-six of these subjects were randomly assigned training in hypnosis prior to the experiment, while subjects were randomly assigned to control ups that did not receive such training. The pnotic training, which averaged about 10 hours subject, was conducted in small groups and utilized a relaxed and permissive approach (see Zimbardo, Maslach, & Marshall, 1972). The training program sampled a wide variety of hypnotic experiences and included as criterion tests (a) the successful completion of posthypnotic suggestions with accompanying amnesia and (b) increased tolerance of ischemic pain (a measure developed by Lenox, 1970). Throughout the experimental session, trained and untrained subjects were treated identically except for a brief hypnotic induction for the trained subjects.

Procedure

The study consisted of two experiments that followed the same procedural format. The testing session was divided into two parts. The purpose of Part 1 was to establish a verbally conditioned arousal response to a specific cue and to demonstrate that this arousal involved substantial physiological changes. In part 2, this arousal was either elicited or not in the presence of a same-sex confederate who was behaving happily or angrily.

Part 1: Physiological arousal. Subjects were told that the study involved several types of individual assessment, including personality characteristics, physiological responsiveness, and learning performance. The subject was seated in a comfortable chair in an acoustic chamber, and the experimenter wiped clean the recording areas with alcohol. Beckman silver–silver chloride skin electrodes (17 mm in diameter) filled with Beckman Electrolyte Gel were attached by adhesive discs to the thenar eminence of the subject's nondominant palm and the volar surface of the two forearms. For the remainder of the period in the acoustic chamber, the subject's heart rate and galvanic skin response (GSR), as measured by skin resistance, were continuously recorded on a four-channel Offner Type R dynagraph with a #9857 cardiotachometer coupler and a #9842 galvanic skin response coupler. Standardized, prerecorded instructions were presented to the subjects over an intercom. The 5-min hypnotic induction procedure (which was also prerecorded) was eliminated for the unhypnotized control groups, who were merely told to relax for an equivalent period of time while baseline recordings were being made.

All subjects then heard the following verbal con-

---

[2] There were no significant differences between the responses of male and female subjects, so their data were combined.

[3] The selection of high-scoring subjects was done for practical reasons, since they can complete the hypnotic training and pass the criterion tests successfully in a shorter period of time than low-scoring subjects. There is no evidence that they differ in substantial ways from the general population as a whole, although they tend to exhibit a greater imagination (Hilgard, 1970).

ditioning instructions:

> In this session, the following reactions will occur whenever you see the word *start*. When you see the word *start*, your heart will beat faster, your breathing will increase, there will be a sinking feeling in your stomach, and your hands will get moist. You will feel all of these sensations as soon as you see the word *start*, and they will last until I say to you, "That's all for now." When I say, "That's all for now," you will return to your normal state and feel relaxed and good. However, when you see the word *start* and experience these reactions, you will not know why you are feeling the way you are, or remember my telling you anything about it.

The four symptoms that were cited in these instructions had all been reported by a pretest sample of volunteer subjects who had received an injection of epinephrine. Also, the relatively quick onset of the hypnotically induced arousal parallels the rapid "rush" that is typical of many people's response to epinephrine.

Subjects then described their current mood state, using the Nowlis Mood-Adjective Checklist (1963). A series of stimulus lights were then individually illuminated. The first of three neutral cues was a red light, the second was a white light, the third was labeled "stop," and the cue word "start" was given as the fourth signal. Following this arousal cue, subjects filled out a second Mood-Adjective Checklist, describing their feelings at that moment. Next, the termination cue was given for the disappearance of any experienced symptoms and for the return to a normal physiological state and a relaxed psychological state. There was a repetition of the posthypnotic suggestion, and then the hypnotic subjects were brought out of their hypnotic state.

Part 2: Emotional arousal. The subject returned to the first room and joined a waiting confederate (ostensibly another subject). In front of each of them was a memory drum, a learning test sheet, and a folder containing bogus test materials, such as Thematic Apperception Test (TAT) pictures, the Stroop color-word test, and a puzzle. The experimenters observed the behavior of the subject and the confederate through a one-way mirror and communicated via an intercom system.

A learning task was introduced in order to have a nonobvious way of presenting the arousal cue without either the confederate or observers being aware of the manipulation. Two 15-word lists were serially presented on the memory drum with a 4-sec exposure for each word and a 1-min recall test administered immediately after each list. The final word on the second list was either the arousal cue word ("start") or a neutral word ("speedy"). Subjects in the aroused and unhypnotized conditions saw the arousal cue word, whereas subjects in the unaroused conditions saw the neutral one. Next, the subject and confederate were told to look through the materials in the folder and were then left alone for 4 min. During this period, the confederate went through a prearranged series of either "angry" or "happy" behaviors.

The confederate's behavior followed the same general pattern in both the happy and angry conditions, although it differed in affect and the reasons given to justify that affect. During the first minute, the confederate worked with the folder materials and made a few comments about them, while in the second minute he or she talked about the experiment and school. During the third minute, the confederate directed some questions at the subject, and during the fourth minute, he or she finished examining the materials and "accidentally" dropped them on the floor. In both conditions, the confederate's affective level was mild at first (annoyance or positive interest) but became more intense over time (visible anger or exuberant laughter). Both confederates explained their emotional reaction in terms of impending tests and term papers. The angry confederate resented the time away from study caused by this uninteresting and slow-paced experiment. The happy confederate enjoyed the temporary distraction from these academic demands that the experiment made possible.

At the end of this emotional modeling period, the pair was separated and the subject was asked to complete two questionnaires, one of which focused on the subject's present physiological state and experienced emotion, while the other assessed reactions to the confederate. Next, the experimenter took the subject to an adjacent room to be interviewed by a clinical psychologist. This person was not affiliated with the experimenters and did not know what had taken place in the experiment. The clinician's task was to learn what the subject was feeling at the time, discover the cause of any expressed affect, and (if the subject was feeling at all distressed) make him or her feel better. The interviews were open-ended, were about 30 min in length, and were tape recorded for subsequent analysis. The purpose of these interviews was to assess whether the amnesia induction was powerful enough to resist skilled probing by someone unconnected with the hypnosis experience.

After the interview was completed, the experimenter entered the room and removed the hypnotic suggestions for the arousal response and the amnesia. Subjects were then questioned further about their reactions to the study. All subjects promised not to talk about the experiment until it was completed. Experimental silence was maintained, and all subjects later participated in an elaborate debriefing session conducted in a series of informal small group sessions. There was no evidence of any emotional carry-over beyond the immediate experimental setting.

Summary of Design

The first experiment consisted of a 2×3 factorial design. There were three levels of arousal—

aroused (hypnotized + arousal cue), unaroused (hypnotized + no arousal cue), and unhypnotized (not hypnotized + arousal cue). There were two levels of confederate emotion, happy and angry. Subjects who were trained in hypnosis were randomly assigned to the four hypnosis groups, and untrained subjects were randomly assigned to the two unhypnotized groups, all with six subjects per cell.

Because the results of this first experiment did not replicate those found by Schachter and Singer (1962) for the "euphoria" treatment, two additional experimental conditions were tested to discover the basis for these differing outcomes. In both conditions, subjects were given the arousal treatment (hypnotized + arousal cue) and were exposed only to the display of happy emotion by the confederate. One of these additional groups (informed arousal) remained aware of the basis for their arousal, since they were not given any suggestion for posthypnotic amnesia. This group parallels that of the informed treatment in the Schachter and Singer (1962) study. The other group (simplified arousal) was given only two physiological symptoms (heart beating faster, respiration increasing), in order to create a more purely neutral arousal. It was conceivable that the other two symptoms (sinking feeling in the stomach, moist hands), although found in reactions to epinephrine, too strongly suggested a negative arousal state. As before, subjects trained in hypnosis were randomly assigned to these two conditions, with six subjects per group.

Results

Physiological Arousal

There was a striking difference in physiological response between the hypnotized and unhypnotized conditions (see Table 1). For each subject, the heart rate record was divided into 5-sec intervals, and both the highest and mean heart rates for each interval were calculated. There were six such intervals following each stimulus, and their individual scores were combined into a total mean score for each stimulus. A repeated measures analysis of variance for the highest heart rate scores showed that there was a significant main effect of visual stimuli, such that the highest heart rate following the arousal cue was significantly higher, $F(1, 34) = 32.88$, $p < .001$,[4] than the highest heart rate following the neutral stimuli (which did not differ from each other). However, there was a significant interaction between stimuli and hypnosis condition, $F(1, 34) = 5.35$, $p < .05$. The F tests for the two hypnosis conditions reveal that this main effect was due entirely to the hypnotized subjects, $F(1, 34) = 37.17$, $p < .001$. The unhypnotized subjects did not show a significant increase in highest heart rate in response to the arousal cue ($F = 2.19$, *ns*). An analysis of mean heart rate revealed exactly the same pattern of results.

Table 1
Conditioned Physiological Arousal

Condition	n	Cue: Neutral	Cue: Arousal	M increase
		Heart rate[a]		
Hypnotized	24			
Mean		80.8	88.0	7.2
High		84.6	94.1	9.5
Unhypnotized	12			
Mean		76.6	78.8	2.2
High		80.6	83.8	3.2

Hypnotized	24	2.6	4.4	1.8
Unhypnotized	12	2.1	2.4	.3

[a] Beats per minute.
[b] Number per period.

A similar pattern of arousal was reflected in the total number of GSRs following each stimulus. There was a significantly greater number of GSRs following the arousal cue than following the neutral stimuli, $F(1, 34) = 20.87$, $p < .001$. However, there was also a significant interaction between stimuli and hypnosis condition, $F(1, 34) = 6.04$, $p < .025$, and the F tests for the two hypnosis conditions show that the main effect was due entirely to the hypnotized subjects, $F(1, 34) = 26.51$, $p < .001$, and not to the unhypnotized group ($F = .40$, *ns*). This difference in arousal response is even more striking given the fact that both hypnotized and unhypnotized subjects showed a more rapid recognition of the cue word (as evidenced by a shorter latency and higher amplitude of the first GSR following the cue).

Two Mood-Adjective Checklists were completed by each subject, one before the

[4] All reported p values are two-tailed.

arousal stimulus and one after. For purposes of analysis, the adjectives on this list were divided a priori into four groups—positive (e.g., affectionate, overjoyed); negative (e.g., angry, clutched-up); active (e.g., energetic, vigorous); and passive (e.g., calm, quiet). Changes in mood responses were assessed by computing separate mean change scores for each category. The changes scores for the hypnotized subjects indicate the marked shift in emotional state that resulted from their arousal. Their mood became significantly more negative, $t(23) = 7.22$, $p < .001$; less positive, $t(23) = 7.68$, $p < .001$; and less passive, $t(23) = 7.68$, $p < .001$. In contrast, the unhypnotized subjects showed no changes on the negative, active, or passive mood indexes, although there was a tendency for them to report less positive feelings, $t(11) = 2.07$, $p < .10$. Overall, the hypnotized subjects showed a more extreme shift on a composite of these four indexes of mood than did the unhypnotized subjects, $F(1, 34) = 17.14$, $p < .001$.

Because hypnotic subjects responded physiologically to the arousal cue in the acoustic sound chamber, it was assumed that they would respond similarly when they again saw this stimulus during the learning task. Unfortunately, we could not directly assess the validity of this assumption because telemetry equipment was not available to us at the time of the study. Nevertheless, two indirect measures of arousal do provide support for our reasoning. One was the subjects' recall performance on the learning task. Since the second of the two lists either did or did not contain the arousal cue, it was predicted that differences in subsequent arousal states might reduce cue utilization and affect the recall process (cf. Easterbrook, 1959). Although there was no between-groups difference in overall recall accuracy on either list (about 60% accuracy), subjects in the arousal groups made significantly fewer errors of commission ($M = .7$) than did the unaroused and unhypnotized groups ($M = 1.7$) on the second learning list, $t(34) = 2.54$, $p < .02$. It appears that subjects performing under the distracting influence of arousal wrote down only the words they had stored in readily accessible memory and then stopped, without making guesses about the remaining words.

The second indirect measure of arousal was part of the final questionnaire. Subjects were given a list of eight physiological symptoms and asked to indicate which (if any) they were now experiencing. The percentage of subjects who checked each symptom was calculated for each of the experimental conditions. From 92% to 100% of the subjects in the aroused conditions reported experiencing each of the four suggested symptoms, whereas only 26% to 52% of the unaroused and unhypnotized subjects reported having even a single one of the symptoms. The between-groups differences between these proportions for each of the four symptoms computed separately are all beyond the .02 level of significance.

Assessment of the success of the posthypnotic suggestion was provided by open-ended questions on the final questionnaire, as well as by the in-depth postexperimental interviews conducted by the clinical psychologist. Both sources of data clearly support the conclusion that these trained hypnotic subjects who were given an amnesia suggestion were unaware of the true cause of their experimentally induced arousal.

Perception of Confederate

A check on the confederate manipulation was derived from the mean score of three bipolar scale items of seven alternatives about the confederate's emotional behavior (sad–happy, angry–peaceful, friendly–unfriendly). These data were, without exception, in opposite directions for subjects exposed to the happy versus the angry confederate. Subjects in the happy condition evaluated the confederate's mood as significantly more positive ($M = +1.2$) than the neutral midpoint of zero, $t(17) = 4.94$, $p < .001$. In contrast, the treatment mean for subjects in the angry condition ($M = -1.5$) was significantly more negative than zero, $t(17) = 7.45$, $p < .001$. The difference between the two confederate conditions is highly significant, $F(1, 30) = 83.16$, $p < .001$.

Table 2
Expressed and Experienced Emotion

Condition[a]	*M* no. of sociable behaviors: Verbal, Confederate: Happy	Verbal, Confederate: Angry	Nonverbal, Confederate: Happy	Nonverbal, Confederate: Angry	Self-reported emotion (happy minus angry)[b], Confederate: Happy	Self-reported emotion (happy minus angry)[b], Confederate: Angry
Aroused	4.4	.7	10.5	.8	−1.0	−1.2
Unaroused	4.3	.4	8.2	.4	+1.8	+2.5
Unhypnotized	2.5	.9	6.0	1.6	+.8	+.4

[a] $n = 12$ for each condition (6 per cell).
[b] Mean scores are based on the Schachter and Singer (1962) index, which ranges from +4 (most happy) to −4 (most angry).

Overt Emotional Behavior

Measures of subjects' behavior were coded by two judges (interrater reliability was at least .80) who observed each subject during the 4-min emotional modeling period. For each of the 4 min, the judges coded the subject's verbal and nonverbal responses. Some of these responses were sociable ones (i.e., smiling, nodding, agreeing with the confederate), while others were not (i.e., disagreeing, ignoring, frowning). The overt behavior of the subjects varied as a function of the confederate's mood, but seemed unaffected by experienced arousal. As shown in Table 2, subjects in the presence of a happy confederate exhibited a significantly higher amount of sociable behaviors than did subjects who were with the angry confederate. This was true for both verbal behaviors, $F(1, 30) = 20.97$, $p < .001$, and nonverbal behaviors, $F(1, 30) = 44.80$, $p < .001$.

Reported Emotional Experience

Two scale items tapping extent of experienced anger and happiness were adopted from Schachter and Singer (1962). To the items, "How irritated, angry, or annoyed would you say you feel at present?" and "How good or happy would you say you feel at present?" subjects responded on 5-point scales ranging from 0 (not at all) to 4 (extremely). Analyses were made of the difference scores (happy–angry), as well as of the happy and the angry ratings separately. A broader portrait of the emotional state of each subject comes from eight additional bipolar scales (e.g., happy–sad, angry–peaceful, confident–apprehensive) with seven response alternatives. These responses were analyzed separately and then combined into a single index of emotional response ranging from extremely negative to extremely positive.

Although the confederate's mood had a demonstrable effect on the subjects' overt behavior, it did not exert the expected influence on their reported emotional state. For the Schachter and Singer index, there was a significant main effect of arousal, $F(2, 30) = 5.35$, $p < .025$. A comparison of means (shown in Table 2) revealed that this was due to the more negative scores of the aroused condition ($p < .005$).[5] Analyses of each of the happy and the angry ratings separately revealed the same significant difference in emotional reactions between the aroused subjects and the other subjects without arousal.

The mean ratings on the eight-scale index of emotional response are shown in Figure 1. Again, there was a significant main effect of arousal condition, $F(2, 30) = 15.94$, $p < .001$, and a comparison of means revealed that the aroused groups reported a significantly more negative emotional state ($p < .001$) than both the unaroused and the unhypnotized groups (which did not differ from

[5] All comparisons between means following a finding of a significant F ratio were performed using Tukey's honestly significant difference test.

each other). This same pattern of results was found for each individual scale. On the overall index, the aroused conditions reported negative emotions that were significantly different from the neutral midpoint of zero, $t(11) = 6.47$, $p < .001$. While the unhypnotized groups were neutral in their emotions (their mean score did not differ significantly from zero), the unaroused subjects rated themselves as feeling a positive emotional state, $t(11) = 2.32$, $p < .05$. Apparently, the unaroused subjects were responding appropriately to the posthypnotic suggestion that they would feel relaxed and good when they came out of hypnosis. The positive feelings of the unaroused group offer a dramatic comparison level for the negative reaction reported by the aroused subjects (despite the same posthypnotic suggestion to feel good and identical prior to hypnotic training). This positive response is particularly noticeable in the unaroused angry condition, although it did not differ statistically from the unaroused happy group. This finding may be due to a contrast effect (the unaroused subjects may have felt particularly good in comparison to the negative reactions of the angry confederate) or to a self-persuasion effect (many of the unaroused subjects made reference to their positive feelings in an attempt to cheer up the angry confederate).

Attribution of Causality

On the final questionnaire, subjects were asked if they knew why they felt as they did and, if so, to state the reason. These responses were scored by judges who were blind to both the purpose of the experiment and the condition of the subject. The aroused subjects always reported reasons for a *negative* emotional state, regardless of the mood expressed by the confederate. Some subjects said they were nervous about performing well on the experimental tests, others said they were feeling tense about upcoming final exams, and still others labeled their arousal as irritation generated by the confederate's "talkativeness." In only a single instance did a subject explicitly state that the confederate's mood determined his own: "The other guy was really hassled—it rubbed off."

The possibility that the posthypnotic suggestion had the effect of blocking any search for an explanation of the experienced arousal, rather than merely preventing the "correct" explanation, does not appear tenable. The number of aroused subjects (67%) who thought they knew the cause of their current feelings was as high as that of the unaroused and unhypnotized groups. However, at no time did the aroused subjects state that the

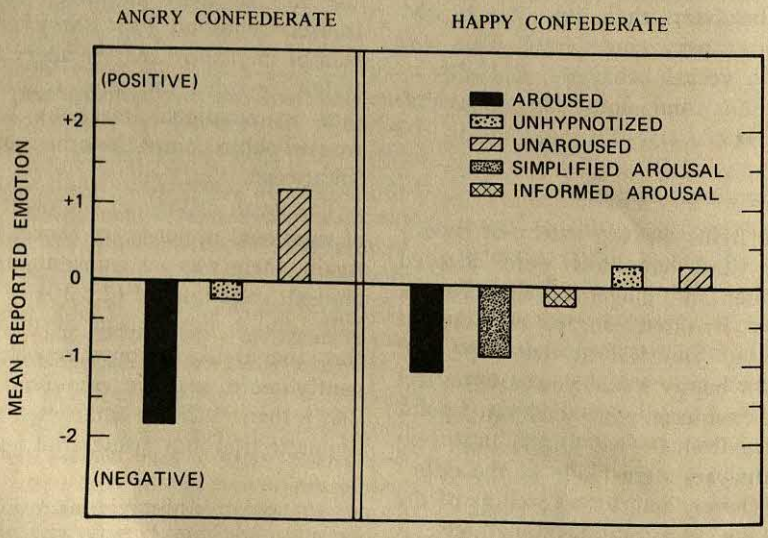

Figure 1. Self-reported emotion (mean self-ratings on an eight-scale index of emotion).

reason was related to the experimentally induced cause of posthypnotic suggestions.

Comparison of Arousal Control Groups

Both of the arousal control groups (informed arousal and simplified arousal) displayed the same pattern of physiological arousal as the happy aroused subjects in the first experiment. They showed the same increase in heart rate, similar changes on the Mood-Adjective Checklist, the same pattern of recall errors, but not a similar change in GSR.[6] On the self-report of physiological symptoms, all of the informed aroused subjects reported experiencing the four suggested arousal symptoms. The simplified arousal subjects reported increased breathing and heart rate, as expected. Surprisingly, however, all of them also reported sweaty palms, and two thirds reported a sinking feeling in the stomach. Even though they had not received any suggestion for these last two symptoms, they generated them spontaneously as correlates of changes in respiration and heart rate. The perception of the confederate by the two control groups was the same as that of the happy aroused group, and they showed the same pattern of sociable behaviors (both verbal and nonverbal) in their interaction with the confederate.

Overall, the two arousal control groups were similar to the happy aroused group in terms of physiological arousal, veridical perception of the confederate, and overt behavior. However, they differed in experienced emotional state. The informed arousal subjects reported a neutral set of feelings (which did not differ from the zero midpoint), as opposed to the negative feelings expressed by the happy aroused group, $t(10) = 1.90$, $p < .10$. As expected, they all stated that the reason for their experienced arousal was the hypnotic suggestion. In contrast, the simplified arousal subjects reported the same negative emotion as the happy aroused group (on each of the self-report measures) and gave the same type of causal explanations. As can be seen in Figure 1, their mean rating on the emotion index was significantly more negative than the neutral midpoint of zero, $t(5) = 4.15$, $p < .01$. In other words, despite a posthypnotic suggestion of only the two most basic physiological concomitants of arousal, these subjects who were unaware of the "appropriate" explanation for their arousal did *not* label their emotion as "happy" in accordance with the available cognitions provided by the confederate's behavior. Rather, they experienced a negative emotional state.

Discussion and Conclusions

The current study was designed as a modified replication and extension of Schachter and Singer's (1962) two-factor theory of emotion. The necessary conditions of strong physiological arousal, lack of an explanation for that arousal, and varied emotional–situational cognitions were all achieved in an experimental setting that controlled for many of the methodological problems of the original study. However, the results reveal a remarkably consistent and coherent pattern of emotional response (especially noteworthy given the small sample size) that is at variance with the interaction pattern predicted by Schachter and Singer. In all cases, subjects with unexplained arousal reported negative emotions, irrespective of the confederate's mood.[7] This finding stands in opposi-

[6] The only inconsistency in the comparison of both the simplified arousal and informed arousal groups with the aroused condition tested initially is the failure of the former to display the same expected changes in GSR. While this may reflect a lower level of physiological arousal, this interpretation is weakened by the fact that these subjects did show the same pattern and degree of change in heart rate and reported awareness of physiological symptoms. A more probable explanation is that since these two groups were run several months after the original conditions, the source of invalidity might have been instrument variation, through unmonitored changes in the electrodes or GSR coupler.

[7] It might be argued that the minimal impact of the confederate on the subject's emotional state was due to the fact that subjects first experienced the physiological arousal while alone (in the acoustic chamber), prior to being aroused for a second time in the presence of the confederate. However, the same pattern of consistently negative affect occurred during the pretesting for the experiment, when subjects received the hypnotic arousal induc-

tion to the position that unexplained physiological arousal is a neutral, energizing variable that does not contribute directly to the qualitative labeling of the emotion. Whereas Schachter and Singer postulated that the lack of explanation for arousal would motivate people to search in an unbiased way for an appropriate cognition, the present study suggests that it not only motivates but biases the search, since it tints perception of that arousal with negative affect. The fact that Marshall and Zimbardo (1979) also found self-reports of negative affect among subjects who lacked an explanation for their strong physiological arousal (and focused their attention on that discordant state) lends additional support to this alternative view.[8]

What might account for this negative emotional bias? One possibility is that since there are more terms referring to negative emotions than to positive ones (e.g., Izard, 1971), people might report negative emotions more often on a purely statistical basis alone. Second, if noticeable physical arousal is indeed a more frequent correlate of negative emotional experiences in everyday life, then the negative affect reported by subjects in the arousal conditions could be regarded as a logical learned response based on prior experiences. Third, as proposed earlier, it may be that unexplained arousal is always characterized by negative affect because it is akin to a state of free-floating anxiety.

The results of the current study suggest that a negative emotional bias will have implications for the person's search for causal information. Subjects who reported negative feelings almost always provided an explanation for them, such as "I'm upset because I don't do well on tests" or "I'm annoyed because this guy keeps joking all the time." In contrast, subjects reporting positive or neutral emotions rarely indicated their cause and gave, instead, such nonexplanatory statements as "I don't know, it's just the way I normally feel."[9] In line with the proposition by Jones and Davis (1965), it seems as if negative experiences are more likely to motivate a search for causal information. People want to know why they feel upset, frightened, or angry, perhaps because they want to control (and thus reduce) the future occurrence of such experiences. On the other hand, they are less motivated to know why they feel happy, pleased, or content, perhaps because they consider such feelings to be their normal baseline condition as opposed to a "deviant" response that demands explanation.

Social Influences on Emotion

An important conclusion to be derived from the current research is that experienced and expressed emotions are not perfectly correlated. Although subjects with unexplained arousal displayed sociable behaviors while

---

tion in the presence of the comparison person. Furthermore, in subsequent research (Zimbardo & Maslach, Note 1), subjects received the hypnotic arousal induction in the presence of at least one other comparison person, and again there was the same pattern of negative affect. The fact that the data from these two studies parallel the results in the current experiment suggests that the procedure surrounding the initial induction (i.e., subject alone vs. subject with confederate) was not a crucial element in the subject's search for an emotional explanation.

[8] It is important to note that Marshall and Zimbardo's (1979) research provides a connecting link between the current study (which found a significant negative emotional bias) and the Schachter and Singer (1962) study (which found no systematic biases from the baseline of the placebo control condition). In the conditions that were an exact replication of Schachter and Singer's experiment, Marshall and Zimbardo "replicated" the original finding of no difference between epinephrine and placebo subjects. Some of the physiological data suggested that the induced arousal was not very strong or salient for many of the subjects, and this may explain why their responses did not differ from the unaroused placebo controls. However, when Marshall and Zimbardo did make the physiological arousal more salient for the subjects, they reported a negative emotional state. The hypnotic manipulation used in the current study also made the arousal state salient for the subjects, and their consistently negative emotional responses replicate those found by Marshall and Zimbardo in their "salient arousal" conditions.

[9] In a personal communication (1976), Gerald Blum reported that subjects in his research on affective arousal (Blum, 1972) showed a similar pattern of responses, giving more causal statements about their negative feelings and fewer about their positive feelings.

in the presence of the happy confederate, their self-reported mood state was not positive. Their comments imply that their overt behavior was more influenced by social contingencies (i.e., norms of social appropriateness) than was their more private feeling state. Such deliberate "management" of one's emotional expression is a fairly common experience for people—as when, for example, one laughs and acts happily with friends even though feeling depressed or hurt by some remark. To assume that one's behavior and self-reported mood are equivalent indexes of emotion is to ignore functional differences between these two response classes.

This issue is relevant for interpreting the results of Schachter's follow-up study on the effects of variations in unexplained arousal on amusement (Schachter & Wheeler, 1962). In this experiment, subjects received an injection of either epinephrine, a placebo, or chlorpromazine (a depressant drug) and were led to believe that there would be no side effects. They then watched an excerpt from a slapstick movie. Whether or not subjects labeled their arousal state in terms of the available cognition of "amusement" was measured by self-reported evaluations of the film and observation of their amusement behavior. Even with large numbers of subjects, there were no significant differences between the three conditions on the self-report measures. The epinephrine subjects and the unaroused placebo controls did not differ on the overall behavioral index (although there was a significant difference on the number of laughs, as opposed to smiles and grins). The major finding was the depressed behavioral response of the chlorpromazine subjects, which may have been a direct somatic effect of the tranquilizer. This lack of correspondence between amusement behaviors and self-reported evaluations of amusement, the lack of variation across treatments in self-report, and the minimal differences between the epinephrine subjects and the placebo controls obviate any serious challenge of the Schachter and Wheeler (1962) study to the results or line of reasoning of the present study.

Another conclusion to be drawn from the current research is that people utilize far more sources of information in generating their emotional explanations than was initially suggested by Schachter and Singer's (1962) analysis. The aroused subjects in the current study perceived correctly the emotion being expressed by the confederate, but they did not necessarily use this emotion to label or explain their own state. Their emotional explanations appeared to be a complex function of their past experience, current life situation, and the immediate situational circumstances, rather than just the mood of the confederate. Not only does this finding extend the notion of "cognitive search" but it also points to the necessity of reconceptualizing the type of information that is presented by the confederate.

Schachter and Singer's model is based on a theory of social comparison (Festinger, 1954) that argues that self-evaluation is often accomplished by comparing oneself with other people. This is particularly true when one has doubts about the appropriateness or correctness of one's feelings, beliefs, or behavior. According to this viewpoint, what is provided by the confederate (the social comparison referent) is *normative* information. The confederate models the "appropriate" way to label the arousal, and the subject adopts a similar response in order to appear (both to self and others) as normal. While normative information indicates how one should feel and act, it does not necessarily indicate *why* one should feel that way. In other words, normative information is not always *causal* information as well. Schachter and Singer argue that the lack of causal information about one's aroused state is what motivates the search for an emotional cognition. However, in postulating that this cognition is obtained via social comparison processes, they are suggesting that the ultimate solution to the search is normative information. If only normative information were needed, then the confederate's reaction would provide a sufficient basis for the subject to evaluate his or her emotion. However, if the subject wants information as to *why* the arousal response is occurring, then the confederate's overt reaction becomes evidence only for the fact that an unknown cause is generating a strong reaction in others as well.

Therefore, the overt reaction is not itself the cause. The subject will look beyond the confederate's reaction for such causal information and may arrive at an emotional cognition that differs from the emotion being expressed by the confederate.[10]

As mentioned earlier, a state of unexplained physiological arousal may not be an appropriate paradigm for studying common emotional experiences. However, the negative emotional bias associated with unexplained arousal suggests that it may be a useful paradigm for studying emotional pathology, particularly if it is viewed as just one of a class of anomalous personal and social experiences. Such anomalous reactions are anxiety provoking because they represent a threat to self-control, and they will usually generate a search for suitable causal linkages. A rational, information-processing model might assume that people engage in a scientific (unbiased) search, in which they seek out and consider all possible evidence in an objective way. However, it may be more correct to assume that they are biased towards certain types of explanations as a result of their past history of reinforcement for particular classes of explanation or ways of thinking about new experiences. We are currently conducting exploratory research on this biasing process, again using hypnosis as a methodological tool to create unexplained arousal.

Furthermore, following from an earlier argument, the study of the process of searching for causal explanations would benefit from an experimental analysis that focused on children's reactions to novel or anomalous events (e.g., first headache or nightmare). This line of work suggests that emotional pathology may not be an impairment of one's cognitive abilities, but a normal cognitive process used to explain an unusual state or event. It extends and expands Maher's (1974) hypothesis about the perceptual genesis of delusional thinking and may provide a unique social psychological perspective on the dynamics of abnormal behavior.

[10] In a personal communication (1977), Stanley Schachter argued that the discrepancy in results between the current research and the Schachter and Singer (1962) study may be due to differences in the timing of the confederate's behavior. In their study, an attempt was made to have the confederate's routine precede or occur simultaneously with the subject's experienced arousal. In the current research, the confederate's behavior followed the onset of arousal by about one minute (the duration of the recall task). According to Schachter, subjects in the current experiment would not have used the confederate's emotion to label their own, since it occurred after the onset of arousal and thus does not qualify as a prior cause. However, this argument has several flaws. First of all, it continues to confuse whether normative or causal information is being provided by the confederate. If it is normative information (as Schachter and Singer's theory implies), then the confederate's behavior is a clue to a possibly shared prior cause but is *not* the cause itself. The confederate's behavior need only occur at about the same time as the subject's arousal to suggest a common, proximal causal event; it is not necessarily required to occur prior to it. Second, Schachter's argument ignores the fact that Marshall and Zimbardo (1979) used the same timing procedure as in the Schachter and Singer study and obtained results supportive of the current research. Third, even if Schachter's argument were correct, it would not explain the highly consistent negative bias of the aroused subjects. If they were indeed forced to interpret their arousal in terms of events preceding the confederate's behavior, then we would expect to find far more variability in the affective quality of their emotional explanations than was actually the case.

Postscript

In their attempt to dismiss the relevance of the data generated by the present paradigm for understanding the role of unexplained arousal in emotion, Schachter and Singer (1979) focus solely on the issue of timing. The points I will address briefly in this rejoinder are designed to (a) clarify the precise timing sequence in the present study; (b) question the generalizability of a model of emotion that depends on such a restricted temporal synchrony between arousal and social cognitions; (c) highlight the importance of the subject's awareness of a discontinuous arousal state; and (d) reaffirm the distinction between two alternative processes a person may engage in when "bodily symptoms search for an explanation"—the normative search and the causal search.

The Timing Sequence and Awareness

In my study, the arousal cue was followed by a 1-min recall test and a 6-sec experimenter statement that "the next part of the study will take a few minutes to set up. In the meantime, you might want to look through the folder materials." The very first minute of the confederate's routine was *not* affectively neutral, since it included smiles, humming, and verbal pleasantries in the happy condition and frowns and verbal expressions of annoyance in the anger condition. Thus, between 1 min, 6 sec and no more than 1 min, 30 sec elapsed from arousal cue to situational manipulation of "happy–angry" social cognition. I submit that this temporal sequence is adequate to allow the confederate's behavior to serve as a reasonable social context for the subject's unexplained arousal.

Indeed, if it is not, then neither is the timing in the original Schachter–Singer (1962) anger condition. The stooge's display of affect in that study might well have occurred *after* most subjects started experiencing their epinephrine-induced reactions. About 1 min is reported to have elapsed before subject and stooge were brought together. Then they had to take some additional minutes to complete the first of five pages of questionnaires, which "start off innocently by requesting face sheet information. . . . The stooge . . . paces his own answers so that at all times subject and stooge are working on the same question" (p. 385). This procedure allows loose subject-controlled temporal variations where Schachter and Singer demand tight experimenter control. Since the onset latency of epinephrine symptoms varies across subjects, some "anger" subjects would have been aroused several minutes before the first anger cognitions were available, some at about the same time, and some slightly after. The timing sequence is less well regulated than in my study and violates Schachter and Singer's condition that social cognitions must precede unexplained arousal in order to be utilized as cues to emotional state. Furthermore, if precise timing is as critical as Schachter and Singer state in their comments on my research, then it must be individually determined for each subject and not left to "on the average" variations in approximate time before symptom onset and approximate time before stooge's display of affect.

Although I address the timing issue directly in Footnotes 7 and 10, Schachter and Singer (1979) have deliberately chosen to dismiss it with their cavalier "footnotes notwithstanding" (p. 990). In rebuttal to their description of the procedures experienced by subjects in the present study and to their comments in their Footnote 1, I assert that the pretest I conducted did *not* involve the critical timing issue raised by Schachter and Singer. Subjects were induced to experience unexplained arousal in the presence of another subject who was already expressing anger or happiness. Similarly, in the unpublished study by Zimbardo and Maslach (Note 1), the timing criticism is again *not* an issue, and the consequence of experiencing unexplained arousal is still negative.

If, as noted earlier, 1-minute differences are so critical, then the generalizability of this model of emotion is severely restricted. It is perception of one's arousal state that motivates a search for a causal explanation. The psychologically relevant variable is the timing of the subject's *awareness* of his of her arousal and available cognitions, and not the time when the drug was injected, when an arousal cue was given, or even when measurable physiological symptoms first appeared. We know that awareness varies considerably across subjects in terms of individual differences in self-monitoring and sensitivity to autonomic discontinuities. The proximal social cognitions that immediately precede this perception of arousal may be the most salient candidates for a causal explanation, but they are not the only ones. Schachter and Singer (1962) manipulated one class of attributes for the experienced arousal, namely a physically present other person. As befits social psychologists, they chose social cognitions as the reasonable context for unexplained arousal. But the subjects could have chosen otherwise, from events in their past or anticipated future, from nonsocial cognitions in the current physical environment, or from health and biological sources. The immediacy of the social cognition increases its probability of being used as the basis for transforming physiological arousal into a psychological emotional state—but it is not a sufficient condition for that to occur. Furthermore, there is no reason to assume that the search process is usually completed in a matter of minutes. Provisional explanations may be generated, tried out, rejected for others, changed by new feedback, and so on. Yes, the confederate in the Schachter–Singer paradigm will be of little effect if he starts after the subject has already chosen a mood label (as Footnote 1 of their 1979 Comments states), but that choice may require some time before it is final, especially in novel situations.

The Normative–Causal Distinction

Schachter and Singer's (1979) Footnote 1 credits me with a "new" distinction between the normative and causal aspects of the cognitive search to account for unexplained arousal. (I will accept that as a compliment and not interpret "new" to mean untenable because not yet empirically validated.) More than the timing issue is involved in recognizing the way these different psychological processes operate when an individual tries to make sense of a bodily state of insufficiently explained arousal.

The normative search entails seeking cognitions that one's reactions are situationally appropriate and socially acceptable. The person wants to know how to behave in an unfamiliar setting or to discover what range of responses is expected. In the process of looking for this "how," the person often comes up with a suitable "what" as well. "What" is the label, or socially agreed upon term, that normalizes an otherwise idiosyncratic and ambiguous reaction.

The causal search entails seeking cognitions that provide information about likely causes and consequences of one's perceived arousal. This search for "why" starts with an effect to be explained in terms of reasonable causal antecedents. Such an analysis need not necessarily involve any social cognitions (although these, of course, are central to any normative search process).

The search for a causal explanation, then, is an attempt to establish effect–cause linkages that help make sense of or bring rationality out of uncertainty. On the other hand, the search for an emotion label and for the "right" way to react may induce emotional contagion merely as a compliance phenomenon.

Schachter has operated primarily out of a social comparison framework since his early work on affiliation and anxiety. Because of this theoretical orientation, he either emphasizes the normative search or fails to acknowledge adequately the causal alternative. When subjects in novel or uncertain situations seek to discover how to behave and what to feel, the confederate's affective display is of little relevance to explaining *why* the subject is suddenly aroused. It serves only a labeling function ("I don't know why, but I am feeling angry, or acting happy," etc.). Or it serves to normalize strange reactions ("I don't know why I'm reacting like this, but at least I'm not the only one").

If the search is normative, then the timing of subject arousal and confederate's behavior should be of little consequence as long as both occur in the same setting (so that the emotional state is perceived as shared), the other person is an acceptable social comparison referent, and there is no other readily available label for the arousal. Timing should be of importance in the causal search only to the extent that the relative contiguity of the confederate's response narrows the search to common elements of the situation that might have caused both it and the subject's own internal reaction.

In conclusion, I am willing to accept the substance of Schachter and Singer's characterization of what my study "proves," when stated in the following form: When subjects are aroused for no apparent reason, they report themselves to be in a "lousy mood" regardless of whether a confederate has been acting happy or angry in their presence and regardless of whether they themselves have displayed happy or angry behaviors. They do so more than do unaroused controls or those who are aroused and know the cause. This is indeed the major finding of my study: that strong unexplained arousal *per se* is typically perceived as a negative state by adults and not as an undifferentiated, affectively neutral state, as the Schachter–Singer model proposes. At this point, I assume further that *both* the search for a causal explanation and the normative search for an appropriate label will be biased in negative directions as a result of prior experiences in which perception of strong arousal is more often associated with aversive events than with pleasant ones.

Affective Consequences of Inadequately Explained Physiological Arousal

Gary D. Marshall and Philip G. Zimbardo
Stanford Medical School
Stanford University

This research reexamined Schachter and Singer's reported demonstration of cognitively influenced physiological determinants in the experience of emotion. In the present study, reports of affective state by placebo-injected and epinephrine-injected subjects, who were misinformed about possible somatic effects and exposed to a euphoric confederate, did not differ. Closer inspection of the Schachter and Singer results also indicates a failure of inadequately explained epinephrine-produced physiological arousal to enhance affective susceptibility to the social environment. Additional evidence provided by the present study reveals a tendency for inadequately explained epinephrine-induced physiological arousal to produce negatively toned reports of affect. The results for additional experimental conditions indicate that (a) manipulations to heighten the experience of physiological arousal produced greater negative affect; (b) similarly, expectation of epinephrine side effects produced negative affect; and (c) the affective tone of the social environment had minimal effect on arousal subjects. These negative affective reactions occurred in a social context where a confederate was perceived to be happy.

The theorizing and research on emotions by Schachter and Singer (1962) must be counted among the primary forces responsible for redirecting the field of social psychology toward a more cognitive orientation (Mandler, 1966, 1975). Their classic study strongly emphasized the important role played by cognitive influences in determining the role of physiological arousal in affective experience.

The Schachter and Singer study examined the contribution of both cognitive and physiological determinants by using a distinctively social psychological research strategy in which both factors were manipulated independently. Physiological arousal was controlled by providing injections of either epinephrine or a placebo. Cognitive factors regarding the arousal were controlled by providing accurate or inaccurate information regarding symptoms. In addition, the social situation was experimentally manipulated by means of a confederate who behaved either euphorically or angrily.

The experience of emotion in this situation was reportedly shown to depend on the interaction of (a) the presence of physiological arousal (via epinephrine injection), (b) the lack of an adequate explanation for this arousal, and (c) the particular affective information provided by the social environment.

This article is based on the first author's doctoral dissertation. The second author served as chairperson of the dissertation committee. The research was supported by Office of Naval Research Contract N000 14-67-A-0112-0041 to Philip Zimbardo. We want to thank Jan Hubbard, Deborah Cowley, David O'Brien, and Jeff Allen for working as research assistants, and Howard Buckley for serving as the physician in the experiment. We also want to thank James McClenahan for making the Student Health facilities available for the research and Carl Thoresen for making available the telemetry equipment. We are grateful to Daryl Bem, Edward Smith, and Karl Pribram for their helpful advice as members of the dissertation committee. We would like to thank Christina Maslach for her helpful comments on this manuscript.

It was intriguing to discover the reported ease with which the same condition of physiological arousal could be steered in as seemingly opposite affective directions as happiness or anger as a result of these cognitive manipulations. The Schachter and Singer report thus constituted a strong argument for a common physiological substrate for different emotions (Fehr & Stern, 1970). It also suggested the existence of an "emotional plasticity" that had apparent therapeutic significance (Nisbett & Schachter, 1966; Ross, Rodin, & Zimbardo, 1969; Storms & Nisbett, 1970, among others).

Despite its importance, there have been no replications of the Schachter and Singer (1962) study reported in the literature. However, several critiques of the study have appeared (Averill & Opton, 1968; Lazarus, 1967; Leventhal, 1974; Plutchik & Ax, 1967; Shapiro & Schwartz, 1970; Stein, 1967). These critiques have questioned the adequacy of some of Schachter and Singer's basic conclusions, and, given the widespread citation of the study, the importance of a direct attempt at replication is obvious.

The present research design was limited to the "euphoric social cognition" condition, because of constraints imposed by the Stanford University Medical School Human Subjects Committee.[1] Furthermore, we chose to concentrate on the information condition that produced the most euphoric outcome for the physiologically aroused subjects in the Schachter and Singer study—the one in which subjects were actively *misinformed* regarding the somatic effects of the epinephrine injection. This was the condition in which the greatest emotional plasticity was reportedly demonstrated. Schachter and Singer actually found only weak treatment outcomes on affect for the physiological arousal manipulation. In the present study, a number of procedural improvements and operational refinements were introduced to provide a better test of the affective consequences of inadequately explained arousal. These changes included forewarning subjects that they were to receive an injection, introducing tasks to support the cover story, obtaining pretest measures in order to directly assess *change* in affect as a result of the manipulations, and continuous physiological monitoring, including additional self-report measures (see Marshall, 1976, for further details).

To further explore the arousal–affect relationship, four additional comparison groups were tested. These were introduced to assess the effects of heightened physiological arousal, the influence of the confederate's behavior, and the effects of information about the likely somatic effects of the injection. The fundamental comparison for assessing inadequately explained physiological arousal, however, is that between the basic placebo subjects and the basic epinephrine-injected subjects (who were misinformed about what to expect from the injection). Both groups were exposed to a euphoric confederate.

Method

Overview

The basic design of the study involved manipulation of physiological arousal via injections of epinephrine or placebo, misinformation about the drug's anticipated somatic effects, and exposure to a confederate who behaved euphorically. In the additional conditions, the following factors were systematically altered: the method of determining epinephrine dosage, the focus of the subject's attention, the confederate's behavior, and the type of somatic effects expected. Heart rate was continuously monitored by telemetry. Pre- and posttreatment self-reports of affect were collected. The subject's behavior while in the presence of the confederate was both rated directly by observers and videotaped for subsequent scoring.

As volunteers for an alleged study of the effects of a special vitamin on vision, a pair of subjects (one a confederate) went through the different

[1] The "angry" condition was disallowed because the committee believed it unethical to induce anger in unsuspecting subjects (assuming the validity of the Schachter and Singer conclusions). The concern of the committee about possible adverse reactions to epinephrine injections in normal young adult males was based on an unreferenced comment in a general pharmacology reference text. In over 100 administrations of epinephrine of the dosages reported in this article, there was not a single adverse reaction. The precautions we took of screening for potential overreactions, availability of a cardiologist, and continuous monitoring of physiological functioning proved to be sufficient safeguards and should be used in further investigations of the psychological effects of this drug in normal populations.
